1.1 SUMMARY

Drug metabolism is a physiological phenomenon in which xenobiotic compounds are chemically transformed into metabolites of the parent drug. Drug metabolism comprises a diverse set of chemical reactions within four general categories: oxidation, reduction, conjugation, and hydrolysis. These general categories of chemical reactions correspond to general categories of enzymes, which are responsible for catalyzing the reactions. The object of drug metabolism is to clear the xenobiotics from the body, so that the metabolites tend to be more polar and soluble than the parent drug, making them easier to excrete. Transporters are now recognized as a necessary component of drug metabolism, since they facilitate penetration of the parent drug into metabolizing organs and passage of ionic metabolites across cell membranes into the excreta. Drug metabolism is important in the clinical action of drugs because it is often the main means by which drugs are cleared from the body, so the rate of metabolism is one determinant of the elimination half-life of the drug. Drug metabolism is additionally important because the metabolites may have pharmacological or toxicological properties, which are superimposed on the clinical profile of the parent drug. For these reasons, the drug discovery process aims to design molecules with rates of metabolism appropriate for clinical use and pathways of metabolism which minimize side effects or toxicities attributable to metabolites. In clinical development, characterization of the metabolic

pathways, the major circulating metabolites, and the enzymes that produce these metabolites is necessary for a full understanding of the clinical profile of a new drug. Accordingly, several types of clinical studies of metabolism are mandated for new drug registration, including identification and quantitation of major circulating metabolites, determination of the major pathways of clearance (CL) and their associated metabolic enzymes, characterization of drug–drug interactions based on metabolic phenomena, and assessment of the extent of excretion of drug-derived materials from the body.

1.2 INTRODUCTION

When an organic compound enters the human body, it is normally (i) utilized as a nutrient, (ii) directly excreted, or (iii) chemically modified and then excreted. In the case of a nutrient, the molecules enter specific biochemical pathways that either split them into small units followed by complete oxidation to generate energy (*catabolism*) or utilize them as precursors for constructing physiological molecules such as nucleic acids, polysaccharides, proteins, and triglycerides (*anabolism*). The overall process of utilization of nutrients is called *intermediary metabolism*. An example is the splitting of dietary fatty acids such as palmitic acid into two-carbon acetyl CoA units that can be oxidized in the mitochondria to produce energy (as ATP).

In cases of nonnutrient compounds (*xenobiotics*), however, pathways for significant energy production seldom exist, although in some cases the body is able to partially metabolize an organic compound for its energy content, as for instance with N-demethylation of drugs (Section 1.3).

The methyl group is released as formaldehyde, which is further oxidized to formate and finally carbon dioxide, generating 2 mol of NADH. However, since 1 mol of NADPH must be invested for the metabolic demethylation, then the net energy production is 1 mol of NADH, equivalent to 3 mols of ATP. Most such reactions of xenobiotics are either energy-neutral (e.g., hydrolyses) or actually energy-consumptive (e.g., hydroxylations), since they produce no energy equivalents, but may use cofactors such as NADPH, PAPS, SAM (*S*-adenosine-L-methionine), or UDPGA, which require cellular ATP equivalents for their synthesis.

With the majority of xenobiotics, only a limited set of nonspecific chemical modifications is possible. This process is called *drug metabolism*, although it occurs with all absorbed foreign compounds, and not just drugs. To avoid confusion with intermediary metabolism, drug metabolism is sometimes called *biotransformation*. However, in fact, there is rarely any serious confusion between these two terms, and the term *biotransformation* is not really descriptive enough to convey a clear meaning in any event. So, most scientists working in this field simply call it *drug metabolism*. For the purposes of this chapter, we make no distinction between xenobiotic chemical

compounds that are unintentionally introduced into the body (e.g., natural plant alkaloids or environmental chemicals) and those that are intentionally dosed (e.g., medicinal drugs). The same CL mechanisms operate on all xenobiotics, and we use the term *drug metabolism* to describe the chemical modification of any nonphysiological compound. Drug metabolism occurs in all species, from bacteria to humans, but our primary focus in this chapter is the human phenomenon, only with reference to other species, as they are relevant to the process of discovery and development of new drugs. An increasing proportion of new drugs are proteins and nucleic acids (i.e., *biologics*), but the scope of this chapter is limited to the discussion of traditional small-molecule organic compounds.

The recognition that foreign substances may be metabolized in the body goes back almost two centuries, and an interesting history of the early discoveries is available in the form of a journal article [1] or website [2]. About 60 years ago, biochemists began to recognize drug metabolism as a distinct field of study. Soon, scientists in academia, pharmaceutical companies, and regulatory agencies realized that characterization of the metabolic fate of drugs was an important component in understanding their clinical profiles. Initially, it was sufficient to merely demonstrate that a dosed drug and/or its metabolites were eliminated from the body in a reasonable amount of time. Next, in the evolution of drug metabolism, there was a need to determine the chemical form of the major drug-related materials in the excreta. Today, the potential role of circulating metabolites in therapeutic action as well as toxicity has become apparent, and a sophisticated quantitative chemical, biochemical, pharmacological, and toxicological description of metabolism is required for the registration of new drugs.

Finally, we can ask “What is the object of drug metabolism?” As can be seen in subsequent sections, drug metabolism is more than just an attempt by the body to “eat” ingested foreign compounds. The existence of a complex, regulated, and interacting set of barriers and CL mechanisms suggests that the object is to chemically and physically limit the entry of these compounds to the body and facilitate their removal from the body. Those compounds that are not clearable by direct excretion in urine or feces are subject to sequential rounds of metabolism, which change their chemical and physical properties until they *can* be excreted. With these thoughts in mind, let us discuss in detail exactly what drug metabolism is and why it is important to the discovery and development of new drugs.

1.3 THE PHENOMENON OF DRUG METABOLISM

Drug metabolism comprises such a rich variety of chemical modifications of organic compounds that it is rare to find a drug that is not subject to some type of metabolic process. Of course, there is a kinetic component of the drug-metabolism process as well, so in some cases the metabolism occurs only slowly. For example, amiodarone is cleared from the body exclusively by metabolism [3], but because the metabolic process is very slow, this drug has a 55-day terminal half-life [4]. In other cases, the direct excretion process is much faster than metabolism and dominates CL. So we find that amoxicillin, for example, is mainly excreted as the intact parent drug in urine [5]. Nonetheless, most drugs are rapidly metabolized as the major route of CL from the body. Although the diverse manifold of possible reactions presents a complex array of

possibilities, we can recognize some patterns, so that it is possible to use relatively few terms to describe virtually all the transformations. In fact, there are only four major categories: oxidations, reductions, conjugations, and hydrolyses.

These four categories of chemical transformation arise from four broad classes of enzymes, which actually accomplish the transformation for a particular drug. It is common, if not universal, for a particular drug to be subject to more than one metabolic conversion. For example, dextromethorphan has two major metabolites, one resulting from N-demethylation and the other from O-demethylation (Fig. 1.1).

As one would expect, some metabolites are the product of sequential operation of two or more of these basic transformations, as shown for loratadine, which undergoes oxidative decarboethoxylation followed by aromatic hydroxylation and finally glucuronidation (Fig. 1.2).

Occasionally, a metabolic pathway apparently not conforming to this fourfold categorization is encountered, as shown in Fig. 1.3.

However, almost always, closer examination shows that the process was actually a diversion during operation of one of the four standard categories [8,9]. In the example in Fig. 1.3, pulegone is first hydroxylated on an allylic methyl group, followed by internal hemiketal formation and dehydrative aromatization to form menthofuran [10].

Figure 1.1 N- and O-demethylation of dextromethorphan [6].

Figure 1.2 Metabolic pathway for loratadine [7].

Figure 1.3 Ring closure of pulegone to menthofuran.

Figure 1.4 Ring contraction of vicriviroc [11].

A more vexing example is provided below by the contraction of a six-membered pyrimidine ring to a five-membered pyrazole ring in the anti-HIV drug vicriviroc (Fig. 1.4). Although no explanation for this reaction had been published, one can write a plausible, albeit complex, metabolic pathway linking the parent drug and the metabolite utilizing only known reactions from the four standard categories (details left as an exercise for the reader).

Although many interesting chemical transformations are known in biochemistry, we limit our discussion here only to ones that have been demonstrated to occur with xenobiotics. Table 1.1 summarizes the main chemical reactions of human drug metabolism. Each metabolic reaction has been given a name descriptive of the overall chemical transformation that occurs, regardless of the internal mechanism by which the transformation was accomplished. However, in many cases, the metabolic reaction has a name commonly used in the published literature of drug metabolism. For example, “introduction of an oxygen atom at an aliphatic position” would typically be referred to as *Hydroxylation*, even though an oxygen atom, not a hydroxyl group was added to the molecule. The common name is given in parenthesis. Note that the drugs and metabolites are drawn in their unionized forms to better see the chemical transformation that has occurred. Although Table 1.1 is intended to be reasonably comprehensive for introductory purposes, it is not exhaustive. A number of unusual examples have been compiled elsewhere [8,9].

Finally, it is worth noting that some metabolic reactions can be reversed, leading to the phenomenon of *futile cycling*. A metabolite that is produced through one of the metabolic reactions in Table 1.1 may be reconverted to the parent drug by another metabolic reaction, with no net chemical transformation. An example is the conversion of a tertiary amine to an *N*-oxide (Reaction I.F). Since some *N*-oxides can be reduced to tertiary amines (Reaction II.B), the result is that the amine appears not to have been metabolized, when in fact two metabolic steps occurred [32]. The existence

TABLE 1.1 Chemical Transformations Comprising Drug Metabolism**I. Oxidations**

A. Insertion of an oxygen atom into an aliphatic C–H bond (aliphatic hydroxylation) (Fig. 1.5)

B. Insertion of an oxygen atom into an aromatic C–H bond (aromatic hydroxylation) (Fig. 1.6)

$Ar-H \rightarrow Ar-OH$ Although this reaction is superficially equivalent to Reaction I.A, the underlying mechanism is quite different, justifying a separate designation.

C. Carbon–carbon bond cleavage (C-dealkylation) (Figs. 1.7 and 1.8)

D. Carbon–heteroatom bond cleavage (N, O, or S-dealkylation) (Fig. 1.9)

Although dealkylation is sometimes presented as a variant of Reaction I.A in which the alkyl group is merely hydroxylated followed by spontaneous dissociation to the observed amine, alcohol, or thiol and carbonyl products, the actual mechanism is distinct, justifying a separate designation.

E. Addition of an oxygen atom to an alkene or alkyne (epoxidation) (Fig. 1.10)

F. Addition of an oxygen atom to a heteroatom (N- or S-oxidation) (Fig. 1.11)

of the separate oxidation and reduction steps can usually be demonstrated by *in vitro* experiments under controlled conditions. Futile cycling may also occur with the hydroxy-to-keto conversion, sulfation/desulfation, phosphorylation/dephosphorylation, and acetylation/deacetylation [33]. An important variation is seen with glucuronidation of a phenolic drug (Reaction III.D), followed by excretion of the *O*-glucuronide into the intestine through the bile. Intestinal bacteria often efficiently hydrolyze glucuronides back to the parent drug (Reaction IV.B), which may be reabsorbed through the intestinal wall [19]. This *entero-hepatic circulation* may be detected by an anomalous pharmacokinetic (PK) profile, and confirmed by collection of bile to confirm the presence of the glucuronide as well as by *in vitro* experiments showing that the parent drug is readily glucuronidated. Another special case of futile cycling is called *redox cycling*, in which hydroxylation of an aromatic ring on a drug produces a hydroquinone, which is then one-electron oxidized by molecular oxygen to a semiquinone radical and then a quinone [34,35]. Quinones are often easily metabolically reduced back to hydroquinones to start a new cycle, which may be repeated many times. This is an especially undesirable type of metabolism, because it amounts to the drug acting as a catalyst to convert oxygen to dangerous *reactive oxygen species* such as superoxide anion radicals, hydrogen peroxide, and hydroxyl radicals. These several examples of futile cycling show that there can be “hidden” metabolism, and some genetically variant enzymes or drug–drug interactions may interfere with one of the counterbalancing reactions, causing unexpected metabolic effects. Thus, drug-metabolism scientists who are developing drug candidates with potentially reversible metabolic pathways normally investigate whether futile cycling is occurring *in vivo*.

1.4 THE DRUG DISCOVERY AND DEVELOPMENT PROCESS

The study of drug metabolism is a distinct academic science including basic research, specialized scientific societies, and dedicated journals. However, as the name suggests, the biggest application of the science of drug metabolism is in the understanding of the clinical actions of new therapeutic agents and in satisfying regulatory requirements for their registration. For this reason, the majority of metabolism data appearing in the literature for specific drugs results from industrial drug development. Accordingly, we briefly outline the new drug discovery and development process to provide the framework for discussion of this important application of drug metabolism.

1.4.1 Discovery

Basic research elucidates the complex biochemical events that comprise a physiological process such as regulation of blood glucose, and identifies key biochemical control points mediated by enzymes or receptors. Drug discovery begins with a new concept for therapeutic intervention of a disease based on the knowledge gleaned from such research. Most drugs exert their pharmacological action by modulating the activity of one of these enzymes or receptors within cells of the abnormally functioning organ. So the next step is *lead generation*, the design or discovery of a small molecule that will bind to the molecular target in such a way as to modulate its activity. Once a lead has been generated, medicinal chemists typically synthesize hundreds to thousands of analogs by systematically varying the structure to create a compound that has

been optimized with respect to potency and selectivity toward the molecular target, PK characteristics, and safety. Numerous *in vitro* and *in vivo* screening assays are established to determine which compounds have these properties in the acceptable range for the intended medical indication [36]. Since drug discovery normally takes place before the clinical phase, the human PK characteristics of a drug candidate must be inferred from *in vivo* animal models or from various human-derived *in vitro* systems [37]. The data output from these screens is used iteratively to design better molecules. Once a discovery compound has been identified with overall favorable “druglike” characteristics (good potency, selectivity, safety, and PK), it is designated as a *clinical drug candidate* and enters the development process [38].

1.4.2 Preclinical Development

Before a new chemical entity can be tested in humans, its safety in various *in vitro* and *in vivo* pharmacological and toxicity tests must be assessed [39]. This includes administration of high doses of the drug candidate to a rodent species (mice or rats) and a large animal species (dogs or monkeys), as well as *in vitro* tests of genotoxic potential (such as the Ames test). In parallel with the safety testing, a large-scale chemical synthetic process must be developed to produce the tens of kilograms of the drug candidate required to conduct clinical trials. Finally, a clinical formulation must be devised that provides adequate and reproducible exposure of subjects in the clinical trials, and animal PK studies are helpful in this design process. Data from the discovery and preclinical activities form the basis of a petition to government health authorities for permission to begin testing in humans. Once this dossier, called the *Investigational New Drug Application* (IND) in the United States, is approved, clinical trials may proceed [40].

1.4.3 Clinical Development

Clinical trials are formally divided into four distinct, but temporally overlapping phases (I–IV), defined by the objectives of each phase [41].

Phase I tests the safety and tolerability of the drug candidate in normal healthy volunteer subjects. The primary goal is to determine the safety profile and the maximum dose that may be safely given to people. An additional goal is the determination of PK parameters, which are needed to plan the next phases. Other phase I PK studies include metabolism and elimination of the drug [42], detection of circulating metabolites of the drug [43], determination of the effect of food on orally administered drugs [44], formulation testing [45], and checking for PK interactions between coadministered drugs [46]. The most common form of PK drug–drug interaction is the competition of two drugs for the same CL mechanism, especially the CYP superfamily of drug-metabolizing enzymes [47]. These interactions, if present, place limitations on which drugs can ultimately be administered together clinically with the new agent [48]. All clinical PK studies rely on some method of quantitation of drug levels in blood or plasma, and the major bioanalytical technique in use today for this purpose is *liquid chromatography coupled to tandem mass spectrometry* (LC-MS/MS) [49,50]. Present technology permits determination of picogram-per-milliliter levels of drug in the presence of many interfering substances, with sample-to-sample cycle times <2 min.

Phase II investigates in limited numbers of patients whether the drug candidate modulates the pharmacological target (*proof of activity*) and whether this activity actually results in the desired therapeutic benefit (*proof of concept*). If proof of concept is established, several dose levels are next assessed for efficacy in patients with the disease to be treated. The optimum dose level is then chosen, based on a balance of benefit and safety. Although the main goal of phase II clinical trials is the determination of efficacy toward the disease indication, PK is a fundamental part of this goal, because to understand the clinical utility of the new drug candidate, it is necessary to define the temporal relationship between plasma levels and the pharmacodynamics of the beneficial effect (PK/PD). A secondary PK goal in phase II is to determine if the disease state affects the PK of the candidate drug compared to the PK seen in healthy subjects.

With an optimized dose identified, *phase III* tests the drug in much larger groups of patients to establish a comprehensive clinical profile of the new drug candidate. Phase III trials are intended to confirm a statistically significant benefit versus either placebo or, more usually, standard-of-care therapy. Additional phase III studies may investigate the variation of therapeutic response and safety in various severities of the disease and in special populations such as ethnic groups or comorbidities. Once phase III is complete, the sponsor of the drug candidate may submit an application (called the *New Drug Application* in the United States) for approval to government health authorities of all countries in which marketing is desired [51].

Phase IV usually occurs once the drug has been approved and is on the market. It involves testing in even larger populations and for longer periods of time, as well as testing against additional disease indications. However, monitoring patients for long-term safety issues (*pharmacovigilance*) may be the most important activity in phase IV, because the number of patients and the length of treatment allow detection of low frequency and/or long-term effects of the new drug that may not have been evident in phase III.

1.5 THE SIGNIFICANCE AND IMPORTANCE OF DRUG METABOLISM

Drug metabolism is centrally important to the clinical utility and effectiveness of most drugs. Metabolism is the main route of CL for nearly three-quarters of marketed drugs [53]. In fact, even the *absence* of metabolism is an important fact to be known about a drug's clinical profile. The importance of drug metabolism in drug action has four general aspects: CL of the drug from the body, pharmacological activity, toxicity, and drug interactions.

1.5.1 Clearance of Drugs from the Body

Persistence of the drug in the body is usually quantitated as the PK half-life ($t_{1/2}$) or the mean residence time (MRT), both of which are typically given in units of hours or days. Persistence is a function of the availability and capacity of the body's CL mechanisms, of which drug metabolism is often the most important.

In the frequent case that CL occurs by enzymatic metabolism of the drug, the rate of metabolism of the drug by the particular enzyme catalyzing the metabolic reaction

is determined by the Michaelis–Menten equation of enzyme kinetics (chapter titled *Enzyme Kinetics of Drug-Metabolizing Reactions and Drug–Drug Interactions*).

$$\text{Rate} = \frac{V_{\max}[\text{Drug}]}{K_M + [\text{Drug}]} \quad (1.1)$$

In Equation 1.1, $V_{\max}$ is the rate that the enzyme can convert drug to metabolite when drug availability is not limiting (i.e., high drug concentrations), and K_M is a constant that determines the drug-concentration dependence of the enzyme rate. We can simplify Equation 1.1 by assuming that drug concentrations are always low compared to K_M (i.e., $[\text{Drug}] \ll K_M$), leading to Equation 1.2.

$$\text{Rate} = \frac{V_{\max}}{K_M} [\text{Drug}] \quad (1.2)$$

Thus, when the assumption of $[\text{Drug}] \ll K_M$ is obtained (a condition that is often true), the rate of metabolism is proportional to drug concentration (i.e., first-order kinetics), and in that case blood levels of the drug are proportional to dose. Since dose-linear PKs is usually a desirable property of a clinical drug, one of the selection criteria for new drug candidates during the discovery phase may be that K_M -values are high compared to the expected maximal clinical blood levels.

Because metabolizing enzymes are usually concentrated in a CL organ (e.g., liver), CL of a drug from the blood is governed by mass transport to the CL organ in addition to the enzymatic capacity of that organ to remove the drug from blood, as expressed in the following relationship.

$$\text{CL} = \frac{f_u \text{CL}_{\text{int}} Q}{f_u \text{CL}_{\text{int}} + Q} \quad (1.3)$$

In Equation 1.3, CL is the rate at which blood is cleared of the drug by the CL organ, with units of L/h. Intrinsic CL (CL_{int}) is the capacity of the organ to clear the drug in the absence of mass transport restrictions on presentation of the drug to the organ. Q is the rate of blood flow to the CL organ and f_u is the fraction of drug not bound to plasma proteins such as albumin [54].

CL can also be expressed as the concentration-normalized rate, so we may define the intrinsic ability of the enzyme to metabolize the drug as the intrinsic CL (CL_{int}) by dividing Equation (1.2) by $[\text{Drug}]$.

$$\text{CL}_{\text{int}} = \frac{V_{\max}}{K_M} \quad (1.4)$$

Substituting Equation 1.4 into Equation 1.3 yields Equation 1.5, which shows that CL is a function of enzyme kinetics and organ blood flows.

$$\text{CL} = \frac{f_u \frac{V_{\max}}{K_M} Q}{f_u \frac{V_{\max}}{K_M} + Q} \quad (1.5)$$

Equation 1.5 can be further simplified by recognizing that many drugs are so-called “low CL” drugs, meaning that the intrinsic CL is low compared to the blood flow.

$$CL = f_u \frac{V_{\max}}{K_M} \quad (1.6)$$

Since half-life is a more intuitive concept for most scientists than CL, we note that for an ideal drug (i.e., one-compartment PKs), the half-life ($t_{1/2}$) of the drug in the body is related to its CL in a reciprocal fashion,

$$t_{1/2} = \frac{0.693 V_d}{CL} \quad (1.7)$$

where V_d is the volume of distribution. Substituting Equation 1.7 into Equation 1.6 yields the final expression.

$$t_{1/2} = \frac{0.693 V_d}{f_u \frac{V_{\max}}{K_M}} \quad (1.8)$$

Equation 1.8 shows that the values of the enzymatic constants $V_{\max}$ and K_M for a particular enzyme–drug pair will determine whether the drug is low or high CL and, therefore, whether the half-life is long or short. Note that Equation 1.8 was derived for the simple case in which $[Drug] \ll K_M$ and $CL_{\text{int}} \ll Q$ in order to arrive at an equation simple enough to be intuitively understood. Omitting those assumptions would make Equation 1.8 more mathematically complex, but would not alter the qualitative conclusion that the half-life of a drug is inversely related to the enzymatic rate of its metabolism. Equation 1.8 is also used in later sections to rationalize the phenomena of drug interactions, induction, and genetic variation in drug metabolism.

During the drug discovery process, Equation 1.8 provides a means for medicinal chemists to adjust the half-life of their drug candidates by changing the molecular structure to reduce $V_{\max}/K_M$ (to increase half-life) or increase $V_{\max}/K_M$ (to decrease half-life). For instance, if the half-life in animals is very short, it is likely to be short in humans as well. Thus, the chemists would try to design a molecule that is less metabolically labile by identifying the point on the molecule that is susceptible to rapid metabolism (the *metabolic hot spot*; e.g., a methoxy group subject to O-demethylation) and replacing it with a molecular configuration that is more metabolically stable (e.g., substituting OCF_3 for OCH_3). The $V_{\max}/K_M$ ratio (i.e., CL_{int}) of a series of modified molecules can be quickly checked with an appropriate *in vitro* system containing the metabolic enzyme responsible for the metabolism (e.g., cytochrome P450 in liver microsomes). Unfortunately, merely replacing the metabolized group with something that is less easily metabolized does not always lengthen the half-life, since metabolism sometimes shifts to another site on the molecule (*metabolic switching*). Thus, a series of molecules must usually be synthesized and tested to find one that is actually metabolized more slowly, and the ability to test many molecules quickly with metabolic enzymes rather than whole-animal studies greatly facilitates this aspect of drug design. Conversely, a candidate molecule may be metabolized so slowly that the expected human half-life would be unacceptably long. In this case, a common approach is for the chemists to introduce a *metabolic soft spot* to provide an easier point for metabolic enzymes to attack the molecule. Again, a series of modifications would usually be tested with enzymes to find one with the right $V_{\max}/K_M$ ratio, as reflected in the observed half-life.

1.5.2 Pharmacological Activity of Metabolites

It is important to note that CL refers to the elimination from the body of a particular chemical compound, in this discussion the parent drug. Thus, chemical transformation to a metabolite is a form of CL, even though the same mass of drug-related material may remain in the body after the metabolism. Consequently, if the metabolite(s) are pharmacologically active, biological effects may continue even after the parent drug has been cleared. Since metabolites are often only subtly different in chemical structure from the parent drug (e.g., conversion of a tertiary amine to a secondary amine by N-demethylation), it is not surprising that some metabolites retain binding affinity for the biological target. These are called *active metabolites*, and they may contribute substantially to the overall pharmacological effect of the administered drug. For example, in the nonsedating antihistamine loratadine shown in Fig. 1.2, the descarboethoxy metabolite also displays prominent antihistaminic activity [7]. Accordingly, characterization and quantitation of metabolites and their residence times in the body are just as important as they are for the parent drug in developing a full understanding of the clinical profile of a new drug candidate.

Sometimes the parent compound itself has essentially no pharmacological activity and must be converted to an active form by metabolism in the body. Such compounds are called *prodrugs*, and they may be used to circumvent barriers of solubility or intestinal absorption. The inactive prodrug compound may have solubility favorable for preparation of a soluble intravenous formulation or membrane permeability that allows for good oral absorption. Once in the body, enzymes chemically change the prodrug to an active compound which is then available to the biological target. For example, as shown in Fig. 1.27 in Table 1.1, the pharmacologically active free acid enalaprilat is released from the inactive prodrug ester enalapril by intestinal, hepatic and plasma esterases. The difference between a compound producing an active metabolite and a prodrug, then, rests in whether the administered agent itself exhibits intrinsic pharmacological activity, but in both cases metabolism is involved in eliciting the full pharmacological action of the drug. An in-between case is that of the anticancer drug tamoxifen, which has an active four-hydroxy metabolite that is 30–100X more potent than tamoxifen itself. Thus, the extent to which an individual patient metabolizes tamoxifen affects the outcome of treatment [55].

1.5.3 Toxicity of Metabolites

A variation on the concept of active metabolites is the case in which the metabolite has different pharmacological activities from those of the parent drug. These different activities arise from binding of the metabolite to receptors other than those that the parent binds, including being less selective for binding to the particular receptor subtype for which the parent drug was optimized. These additional undesired activities would manifest as *adverse effects* of the drug and could range from mild to severe. Some metabolites can even display frank toxicity, such as cyanide metabolically released from the industrial chemicals acetonitrile and acrylonitrile [56,57] or the nephrotoxin thioformamide formed from the antihelminthic thiabendazole [58].

An important but currently poorly understood type of toxicity due to metabolism results from the production of *reactive metabolites* [59]. These are metabolites that have chemical reactivity that causes them to react with normal physiological compounds present in cells. The normal cellular components with which these metabolites

react are typically nucleophiles (amines, thiols, alcohols, phenols, or nucleobases) and range from small molecules such as glutathione to macromolecules such as proteins or nucleic acids. In each case, the normal component is chemically altered in such a way that its usual function in cellular biology is altered or disrupted. We can, somewhat arbitrarily, further distinguish between reactive metabolites and reactive intermediates. A reactive *intermediate* is so unstable that it immediately reacts with chemical moieties inside the active site of the enzyme that formed it. Conversely, a reactive *metabolite* is stable enough to be released from the active site of the enzyme that formed it and, is thus, potentially able to react with any target molecule in the cell. Numerous examples of reactive intermediates are known, especially with the cytochrome P450 class of enzymes, which are often victims of irreversible metabolism-based inhibition because of the formation of extremely reactive electrophilic intermediates resulting from oxidation of certain drugs. An example is the reactive oxirene resulting from oxidation of the acetylene functional group of ethynylestradiol by CYP3A5 [52]. Likewise, many examples of reactive metabolites have been reported, of which the classic example is *N*-acetyl phenyliminoquinone (NAPIQ), formed by sequential oxidations and conjugations of the commonly used painkiller acetaminophen (paracetamol) [59]. NAPIQ has been shown to covalently bind to an array of intracellular nucleophiles.

With each type of metabolite-derived toxicity, characterization of metabolites would be necessary to fully understand the clinical profile of a drug. International regulatory authorities have recognized this fact by issuing guidances to developers of new drugs, requiring characterization of the toxicological properties of major metabolites circulating in blood in humans. The central dictum is that these major human metabolites must also be present in the circulation of preclinical species used for assessment of safety of new drugs, at exposure levels at least equal to those in humans. Metabolites that are unique to humans may require synthesis and direct dosing for assessment of safety in animals [60,61].

1.5.4 Drug Interactions Related to Metabolic Processes

The final area of importance of human drug metabolism is the occurrence of *PK drug–drug interactions* arising from modulation by one drug (the *perpetrator* drug) of the catalytic activity of a drug-metabolizing enzyme that is involved in the CL of a second drug (the *victim* drug). These modulations take two forms: *inhibition* and *induction* (chapters titled *Enzyme Kinetics of Drug-Metabolizing Reactions and Drug–Drug Interactions*).

Inhibition arises from the fact that drug-metabolizing enzymes are generally nonspecific and typically recognize multiple drugs as substrates. Thus, when two or more drugs are in the body simultaneously, they may act as competitive substrates for one of these enzymes (chapter titled *Enzyme Kinetics of Drug-Metabolizing Reactions and Drug–Drug Interactions*). Modifying Equation 1.8 by the form of the Michaelis–Menten equation that describes competitive inhibition, we can derive Equation 1.9, which shows the effect on the half-life of a drug by a competitive drug, I.

$$t_{1/2} = \frac{0.693V_d}{f_u \frac{V_{\max}}{K_M \left(1 + \frac{[I]}{K_i}\right)}} \quad (1.9)$$

Equation 1.9 shows that the clinical effect of the presence of a second drug I with an inhibition constant K_i is to increase the elimination half-life of a drug, depending on the magnitude of the ratio $[I]/K_i$. Often there is also a concomitant increase in $C_{\max}$. The increased exposure of the patient to the victim drug may result in adverse events or toxicity, so the drug–drug interactions due to inhibition of metabolism are an important safety concern for regulatory authorities. Accordingly, another metabolism-related selection criterion for new drugs is that $[I]/K_i$ should be $\ll 1$, and K_i -values are routinely measured for the most important drug-metabolizing enzymes when a sponsor proposes to bring a new drug candidate to clinical trials. Equation 1.9 assumes *reversibility* of the mutual inhibition between two drugs, so an important adjunct to measurement of K_i -values is the determination that the new drug candidate does not exhibit *metabolism-based inhibition*, which is *irreversible* in nature (also called *time-dependent inhibition*). Assessment of drug–drug interactions due to inhibition of CL by a metabolism-based inhibitor involves a different, more complex mathematical approach [62].

Drugs may also pharmacokinetically interact because of upregulation of the steady-state level of a metabolic enzyme, a phenomenon known as *enzyme induction* (chapter titled ***Transcriptional Regulation of Cytochrome P450 Genes***). The upregulation can occur through a variety of mechanisms, including (i) activation of xenobiotic-sensing receptors resulting in increased expression of the enzyme [63] and (ii) decrease of the cellular degradation rate of the enzyme. Induction usually requires several days of exposure to the inducing drug before the cell fully responds to the stimulus and a new steady-state level of the enzyme is attained. In Equation 1.8, $V_{\max}$ may be factored into $k_{\text{cat}} \cdot E_{\text{tot}}$, where k_{cat} is the catalytic rate constant of the enzyme and E_{tot} is the total amount of enzyme present in the system. If E_{tot} in the CL organ is increased by induction, then the total activity, as measured by $V_{\max}$ will increase. An increase in $V_{\max}$ translates to an increase in CL of the victim drug, a decrease in half-life and a possible decrease in $C_{\max}$ is obtained. This reduced exposure may result in loss of efficacy of the victim drug, so induction of drug-metabolizing enzymes is also an important concern for regulatory authorities. Since the induced enzyme may also be responsible for the metabolism of the inducing drug itself, this phenomenon is sometimes manifest as an adaptive response called *autoinduction*. Sequential doses of an autoinducing drug lead to lower $C_{\max}$ - and AUC-values of that drug. It is possible for autoinduction to be so severe that the drug becomes ineffective after a few doses. Thus, it is important in drug discovery to detect potent enzyme inducers and avoid advancement of such compounds into clinical development. Potent inducers of cytochrome P450 enzymes can be eliminated by higher-throughput *in vitro* assays with gene-reporter assays linked to receptors such as PXR (pregnane X receptor) (Section 1.6.5).

1.6 THE BIOCHEMICAL PROCESS OF DRUG METABOLISM

1.6.1 Anatomical Sites of Drug Metabolism

Where does drug metabolism occur in the body? Some level of drug-metabolism activity can be found in essentially every tissue, but the highest specific activities are associated with organs that interface with the environment: gut, liver, kidneys, skin, lungs, nasal mucosa, and so on. This makes sense if we accept that the object of drug

metabolism is to minimize systemic exposure of the body to xenobiotics. Thus, the first line of defense is to prevent or at least limit entry into the body. This is the function of the various efflux transporters that pump chemicals that have permeated the first layer of cells in these organs. We may consider drug metabolism to be the second line of defense, since generally the enzymes of drug metabolism are intracellular, so that only compounds not efficiently excluded by efflux transporters are subject to drug metabolism. This distinction of first and second lines of defense is somewhat arbitrary, since xenobiotics are not all subject to efflux transport or metabolism during initial organ penetration, but it provides a useful conceptual framework for thinking about the process and is reasonably accurate for many drugs.

Since the greatest absolute amounts of xenobiotics usually arrive by oral ingestion, the intestine and liver are of special importance for the barrier function, and the majority of drug-metabolizing capacity may be found there. An orally ingested xenobiotic must survive stomach acid and intestinal digestive enzymes such as proteases, lipases, and other hydrolases. Then it faces the intestinal wall that is designed to be impermeable to foreign substances, especially highly charged, hydrophilic, or high molecular weight compounds. And those molecules that pass through these two barriers still must elude the efflux transporters. Nonetheless, the majority of xenobiotics actually do survive this gauntlet of exclusion processes and are absorbed into the body, explaining why another type of high capacity barrier (drug metabolism) is necessary in intestine and liver. The process of interception and elimination of molecules that manage to penetrate the intestinal epithelium in order to prevent their ultimate entry into the systemic circulation is called the *first-pass effect*. The physiological purpose of intestine and liver drug metabolism is to *maximize* the first-pass effect. Conversely, the problem faced by the medicinal chemists and pharmaceutical scientists is to *minimize* the first-pass effect, so that a high percentage of the dosed medicine can actually reach the systemic blood stream. Thus, in order to achieve good oral bioavailability, drug discovery teams usually seek to design molecules that are metabolized at only moderate rates.

Once a drug enters the bloodstream, the body begins clearing the compound either by direct excretion or by metabolism followed by excretion. Both of these processes occur in the liver and kidney, but with organ differences. The liver can utilize uptake transporters to bring compounds from the blood into liver cells, where they can be directly excreted through the action of efflux transporters or metabolized by the versatile hepatic drug-metabolizing enzymes. The kidney, on the other hand, can directly excrete a drug into urine by the process of glomerular filtration and by secretion into urine from renal cells by efflux transporters. Kidney also contains a number of drug-metabolizing enzymes, but not the same set or the same densities as liver. Again, for many drugs the direct excretion processes in liver and kidney are ineffective for CL, and molecules must first be metabolized. Metabolism frequently makes a drug more polar and water soluble, facilitating transporter-mediated excretion. In addition, polar metabolites are usually less bound to plasma proteins compared to the parent drug, facilitating their filtration in the kidney. In fact, in this context, metabolism is historically described as occurring in two steps, *phase I* and *phase II*, although more recently this distinction has come into question [64]. Phase I enzymes introduce a polar site into the molecule, for instance, by hydroxylation at a hydrophobic region of the molecule or by dealkylation of an amine or ether functionality to uncover a secondary amine or hydroxyl group. Sometimes phase I metabolism sufficiently increases water solubility that the polar metabolite can either diffuse out of the cell membrane directly into bile or blood

or move to a transporter and be secreted. At other times, however, the metabolite is still too insoluble to be mobilized and continues to mainly associate with cellular membranes. These hydrophobic metabolites may then be recognized as substrates by the phase II enzymes, which add a very polar or even ionic group to make a secondary, conjugated metabolite that is usually excretable in bile or urine. Examples of these more soluble conjugates are glucuronides and sulfates, both of which are negatively charged at pH 7. Thus, we see that metabolism by phase I and/or phase II enzymes followed by excretion of the solubilized metabolites is the most important means of CL of the majority of xenobiotics. A more complete statement of the problem faced by a drug discovery team, then, is to find the right balance between metabolism slow enough that the first-pass effect is low but fast enough that compounds not directly excretable can be metabolized and excreted in a reasonable amount of time.

1.6.2 Subcellular Localization of Drug Metabolism

Taking hepatocytes as the archetypical drug-metabolizing cells, the greatest variety of reactions and capacity for CL are in the smooth endoplasmic reticulum (SER) and the cytosol. Certain special reactions, such as β -oxidation, occur mainly in the mitochondria and peroxisomes. Accordingly, when we wish to study metabolism in an *in vitro* system so that we can control most variables, we use hepatocytes to simultaneously evaluate all possible metabolic routes. Often, however, we want to limit the experimental question to only certain metabolic pathways. In that case, we need to use a subcellular fraction. Hepatocytes can be lysed by homogenization of liver tissue, followed by differential centrifugation to segregate the desired subcellular fraction [65]. By this means, we can prepare the so-called *S-9 fraction* (supernatant from $9,000 \times g$ sedimentation), which contains *cytosol* and liposomal fragments of the smooth endoplasmic reticulum called *microsomes*. *S-9* provides convenient access to almost all important drug-metabolism pathways. Microsomes can be separated from cytosol by more forceful sedimentation of the *S-9* fraction at $105,000 \times g$, allowing us to separately interrogate both the soluble and membrane-bound drug-metabolism enzymes.

1.6.3 The Enzymes of Drug Metabolism

As mentioned above, almost all drug metabolism is mediated by enzymes that fall into a few general classes. Table 1.2 summarizes these classes and a few important features of each enzyme type in the class. In most cases, it is easy to match up an enzyme type with each of the reactions shown in Table 1.1, and the two tables have been arranged in parallel to facilitate this matching. In drug development, it is necessary to identify the enzymes mediating the metabolism of drug candidates, because this information promotes an understanding of several aspects of the clinical behavior of drugs, including genetic variation, drug–drug interactions, time-dependent inhibition, autoinduction, and the effect of disease on a patient’s ability to clear the drug.

Most of the enzymes in Table 1.2 exist in *superfamilies* of closely related proteins, often called *isozymes* or *isoforms*, with different but sometimes overlapping substrate preferences. The enzymes in a superfamily are typically given a designation of the form “*nLm*”, where “*n*” and “*m*” are numbers (1, 2, 3, etc.) and “*L*” is a letter (A, B, C, etc.). The “*n*” designates the family, “*L*” the subfamily, and “*m*” the specific

TABLE 1.2 Summary of Major Enzymes Mediating Human Drug Metabolism

Oxygenases, Oxidases, and Dehydrogenases*Cytochrome P450 (CYP)^a*Typical reaction: $\text{R-H} + \text{O}_2 + \text{NADPH} + \text{H}^+ \rightarrow \text{R-OH} + \text{H}_2\text{O} + \text{NADP}^+$

Prosthetic group: Heme

Required cofactors: O_2 , NADPH, CPR, and cytochrome b_5 (with some substrates)

Tissue expression: Liver and most other tissues

Subcellular localization: Endoplasmic reticulum

*Flavin-Containing Monooxygenase (FMO)^b*Typical reaction: $\text{R}_3\text{N} + \text{O}_2 + \text{NADPH} + \text{H}^+ \rightarrow \text{R}_3\text{N}^+-\text{O}^- + \text{H}_2\text{O} + \text{NADP}^+$

Prosthetic group: FAD

Required cofactors: O_2 and NADPH

Tissue expression: Liver

Subcellular localization: Endoplasmic reticulum

*Aldehyde Oxidase (AOX)^c*Typical reaction: $\text{RCH=O} + \text{H}_2\text{O} + \text{O}_2 \rightarrow \text{RCOOH} + \text{H}_2\text{O}_2$

Prosthetic group: Molybdenum, [2Fe-2 S] centers and flavin

Required cofactors: O_2

Tissue expression: Liver and other tissues

Subcellular localization: Cytosol

*Monoamine Oxidase (MAO)^d*Typical reaction: $\text{RCH}_2\text{NH}_2 + \text{H}_2\text{O} + \text{O}_2 \rightarrow \text{RCH=O} + \text{NH}_3 + \text{H}_2\text{O}_2$

Prosthetic group: Flavin

Required cofactors: O_2

Tissue expression: Many tissues

Subcellular localization: Mitochondria

*Xanthine Oxidase (XOR)^e*Typical reaction: $\text{xanthine} + \text{H}_2\text{O} + \text{O}_2 \rightarrow \text{uric acid} + \text{H}_2\text{O}_2$

Prosthetic group: Molybdenum, [2Fe-2 S] centers and flavin

Required cofactors: O_2

Tissue expression: Liver

Subcellular localization: Cytosol

*Alcohol Dehydrogenase (ADH)^f*Typical reaction: $\text{R-CH}_2\text{-OH} + \text{NAD}^+ \rightarrow \text{R-CH=O} + \text{NADH} + \text{H}^+$

Prosthetic group: None

Required cofactors: NAD^+

Tissue expression: Liver

Subcellular localization: Cytosol

*Aldehyde Dehydrogenase (ALDH)^g*Typical reaction: $\text{R-CH=O} + \text{NAD}^+ + \text{H}_2\text{O} \rightarrow \text{R-COOH} + \text{NADH} + \text{H}^+$

Prosthetic group: None

Required cofactors: NAD^+

Tissue expression: Liver

Subcellular localization: Cytosol

TABLE 1.2 (continued)**Reductases***Aldo-Keto Reductase (AKR)^h*Typical reaction: RCH=O or $\text{R}_2\text{C=O} + \text{NADPH} + \text{H}^+ \rightarrow \text{RCH}_2\text{OH}$ or $\text{R}_2\text{CHOH} + \text{NADP}^+$

Prosthetic group: None

Required cofactors: NADPH

Tissue expression: Liver and other tissues

Subcellular localization: Cytosol

*Cytochrome P450 (CYP)ⁱ*Typical reaction: $\text{ArN} \rightarrow \text{O} + \text{NADPH} + \text{H}^+ \rightarrow \text{ArN} + \text{H}_2\text{O} + \text{NADP}^+$

Prosthetic group: Heme

Required cofactors: NADPH and CPR (hypoxic conditions)

Tissue expression: Liver and most other tissues

Subcellular localization: Endoplasmic reticulum

*Cytochrome P450 Reductase (CPR)^j*Typical reaction: $\text{ArN} \rightarrow \text{O} + \text{NADPH} + \text{H}^+ \rightarrow \text{ArN} + \text{H}_2\text{O} + \text{NADP}^+$

Prosthetic group: FMN and FAD

Required cofactors: NADPH

Tissue expression: Liver and most other tissues

Subcellular localization: Endoplasmic reticulum

*Quinone Reductase (NQO1)^k*Typical reaction: quinone + NADPH $\rightarrow$ hydroquinone + NADP⁺

Prosthetic group: Flavin Required Cofactor: NADPH

Tissue expression: Liver and other tissues

Subcellular localization: Cytosol

Transferases*N-Acetyl Transferase (NAT)^l*Typical reaction: $\text{Ar-NH}_2 + \text{AcSCoA} \rightarrow \text{Ar-NHCOCH}_3 + \text{CoASH}$

Prosthetic group: None

Required cofactors: AcSCoA

Tissue expression: Liver and other tissues

Subcellular localization: Cytosol

*Adenosine Kinase (AK)^m*Typical reaction: Base-Ribose-OH + ATP $\rightarrow$ Base-Ribose-OPO₂H₂ + ADP

Prosthetic group: None

Required cofactors: ATP

Tissue expression: Liver and other tissues

Subcellular localization: Cytosol

*Catecholamine O-Methyl Transferase (COMT)ⁿ*Typical reaction: A catechol + SAM $\rightarrow$ a guaiacol + S-adenosyl-L-homocysteine

Prosthetic group: None

Required cofactors: SAM

Tissue expression: Liver and other tissues

Subcellular localization: Both cytosol and endoplasmic reticulum

*Glutathione S-Transferase (GST)^o*Typical reaction: $\text{R-X} + \text{GSH} \rightarrow \text{R-SG} + \text{HX}$ (X is a leaving group such as halogen)

(continued overleaf)

TABLE 1.2 (continued)

Prosthetic group: None
Required cofactors: GSH
Tissue expression: Liver, kidney, and other tissues
Subcellular localization: Cytosol
<i>Sulfotransferase (SULT)^p</i>
Typical reaction: $\text{Ar-OH} + \text{PAPS} \rightarrow \text{Ar-OSO}_3\text{H} + \text{adenosine-3', 5'-diphosphate}$
Prosthetic group: None
Required cofactors: PAPS
Tissue expression: Liver and intestine
Subcellular localization: Cytosol
<i>Thiopurine S-Methyl Transferase (TPMT)^q</i>
Typical reaction: A thiopurine-SH (or other R-SH) + SAM $\rightarrow$ a thiopurine-SMe + S-adenosyl-L-homocysteine
Prosthetic group: None
Required cofactors: SAM
Tissue expression: Liver, kidney, and erythrocytes
Subcellular localization: Cytosol
<i>UDP-Glucuronosyl Transferase (UGT)^r</i>
Typical reaction: $\text{R-OH or Ar-OH} + \text{UDPGA} \rightarrow \text{alkyl or aryl } \beta\text{-D-glucuronide} + \text{UDP}$
Prosthetic group: None
Required cofactors: UDPGA
Tissue expression: Liver and intestine
Subcellular localization: Endoplasmic reticulum
Condensation
<i>Amino Acid Conjugation^s</i>
Typical reaction:
$\text{Ar-COOH} + \text{H}_2\text{N-CHR-COOH} + \text{ATP} \rightarrow \text{Ar-CONH-CHR-COOH} + \text{AMP} + \text{H}_4\text{P}_2\text{O}_7$
Prosthetic group: None
Required cofactors: glycine or taurine, ATP, and CoASH
Tissue expression: Liver
Subcellular localization: Mitochondria
Hydrolases
<i>Alkaline phosphatase (AP)^t</i>
Typical reaction: $\text{RO-PO}_3\text{H}_2 + \text{H}_2\text{O} \rightarrow \text{ROH} + \text{HOPO}_3\text{H}_2$
Prosthetic group: None
Required cofactors: None
Tissue expression: Intestinal lumen
Subcellular localization: Epithelial brush border
<i>Amidase (AADAC)^u</i>
Typical reaction: $\text{Ar-NHCOCH}_2\text{R} + \text{H}_2\text{O} \rightarrow \text{Ar-NH}_2 + \text{RCH}_2\text{COOH}$
Prosthetic group: None
Required cofactors: None
Tissue expression: Liver
Subcellular localization: Endoplasmic reticulum
<i>Arylsulfatase (ARS)^v</i>
Typical reaction: $\text{Ar-OSO}_3\text{H} + \text{H}_2\text{O} \rightarrow \text{Ar-OH} + \text{HOSO}_3\text{H}$

TABLE 1.2 (continued)

Prosthetic group: None
 Required cofactors: None
 Tissue expression: Liver
 Subcellular localization: Endoplasmic reticulum and lysosomes

Carboxylesterase (CES)^w

Typical reaction: $\text{RCOOR}' + \text{H}_2\text{O} \rightarrow \text{RCOOH} + \text{R}'\text{OH}$

Prosthetic group: None
 Required cofactors: None

Tissue expression: Liver and many other tissues
 Subcellular localization: Cytosol and endoplasmic reticulum

Epoxide hydrolase (EH)^x

Typical reaction: Epoxide + $\text{H}_2\text{O} \rightarrow \text{trans-1,2-diol}$

Prosthetic group: None
 Required cofactors: None

Tissue expression: Liver and other tissues
 Subcellular localization: Endoplasmic reticulum

 β -Glucuronidase (β -Gluc)^y

Typical reaction: Alkyl or aryl β -D-glucuronide + $\text{H}_2\text{O} \rightarrow$ D-glucuronic acid + alcohol or phenol

Prosthetic group: None
 Required cofactors: None

Tissue expression: Liver, kidney, and intestinal lumen
 Subcellular localization: Endoplasmic reticulum and lysosomes in liver and kidney; secreted by *Escherichia coli* in intestine

enzyme. The most widely recognized example is the cytochrome P450 (CYP) superfamily (chapter titled *Structure and Function of Cytochrome P450 Enzymes*). The human genome is known to contain 57 functional CYP genes [66], of which approximately a dozen encode enzymes mainly involved in drug metabolism [94]. Arguably, the most important of the cytochrome P450 enzymes is CYP3A4, often truncated to just 3A4 when the context is understood to be a CYP enzyme. Among the “drug-metabolizing” CYPs, it is common for more than one to be capable of metabolizing a particular drug, although one particular CYP enzyme may make the biggest contribution to the metabolism [11]. Thus, for drug-development purposes, a complete description of the enzymes mediating metabolism must include not only which enzyme type is involved (in this case, CYP) but also which particular CYP enzymes are most responsible for the metabolism of the candidate drug (e.g., enzymes 2C9, 3A4, and 3A5). This *reaction phenotyping* is a rigorous process of testing the ability of various CYP enzymes to metabolize the drug candidate, with multiple reagents, techniques and sources of enzymes [94] (see Volume III). Reaction phenotyping is required for most of the important drug-metabolizing enzymes, to the extent that the state of knowledge of each particular enzyme type allows. For instance, as with the CYPs, drugs metabolized by UDP-glucuronosyl transferase (UGT) also require reaction phenotyping [95]. Many drug-metabolizing enzymes have been cloned and heterologously expressed and are commercially available as single enzymes, greatly facilitating reaction phenotyping and other preclinical drug-metabolism purposes [96]. It is also possible to directly isolate the requisite enzymes from human liver [97], but this is seldom done since it is slow, labor intensive, and requires a source of fresh human tissue.

In addition to the existence of multiple enzymes in a given family, some of the enzymes exhibit allelic variants in their genes across populations. Some of these variants translate to proteins that have reduced or no catalytic activity, but in other cases the variant allele is the result of gene duplication leading to overexpression of the active enzyme. This phenomenon is called *genetic polymorphism*, and it can result in individuals who are *poor metabolizers* (homozygous for the defective gene), *intermediate metabolizers* (heterozygous), *extensive metabolizers* (homozygous for the wild-type gene), and *ultrarapid metabolizers* (carriers of the gene-duplication allele). Since the CYP enzymes are so important in human drug metabolism, polymorphism in the CYPs is especially significant [98] (chapter titled *Cytochrome P450 Polymorphisms*). As mentioned in Section 1.5.4, $V_{\max}$ in Equation 1.8 may be factored into $k_{\text{cat}} \cdot E_{\text{tot}}$, allowing us to rationalize the effect of genetic polymorphisms on the half-lives of drugs that mainly depend on the polymorphic enzyme for their metabolism. Some genetic polymorphisms result in expression of inactive enzyme (i.e., $k_{\text{cat}} \sim 0$), while in other cases there is reduced expression (i.e., $E_{\text{tot}} \sim 0$). In either case, $V_{\max}$ is reduced, and individuals carrying such an allele exhibit increased half-life compared to the general population. The opposite is true for the ultrarapid metabolizers, where the active enzyme is overexpressed (i.e., $E_{\text{tot}} \gg$ normal population). These very real effects on the clinical PKs of some drugs in certain individual patients are important reasons to characterize the enzymology of metabolism of new drug candidates. Consequently, during the discovery process, we try to design compounds that do *not* mainly depend on a single, polymorphic enzyme for their CL.

1.6.4 The Role of Transporters in Drug Metabolism

Transporters are ubiquitous proteins in the body, which move molecules from one side of a barrier membrane to the other (see Volume II). Again taking hepatocytes as the typical drug-metabolizing cell, *uptake* transporters move drug molecules from the blood to the interior of the hepatocytes, while *efflux* transporters export drug or metabolite molecules from the cell interior to the blood or bile [99]. Some drug molecules readily penetrate cell membranes by passive diffusion, while others, with poor membrane permeability characteristics, may require the assistance of a transporter. Uptake transporters, then, could be called *phase 0* of drug metabolism, since they move drugs into cells, where the main drug-metabolizing activities are located.

Analogously, efflux transporters could be called *phase III* of drug metabolism. Once metabolism has occurred, removal of drug-derived material is not complete until the metabolites are moved from the interior of the cells to the excreta (bile, feces, and urine). The chemical modifications that make metabolites more water soluble also make them less permeable through cell membranes. Thus, the efflux transporters complete the process for metabolites that cannot independently diffuse through membranes and out of cells. A particularly important efflux transporter is *P-glycoprotein* (P-gp or MDR1), located on the intestinal epithelium, liver canaliculae, kidney proximal tubules, and brain endothelium. This transporter can pump many types of xenobiotic molecules and metabolites out of cells as a means of exclusion or elimination [100].

As with drug-metabolizing enzymes, transporters are subject to the phenomena of competitive inhibition and induction, creating a second type of metabolism-based drug–drug interaction [101]. Also, most, if not all, transporters have allelic variants resulting in polymorphic functionality [102]. This complicated *metabolism-transporter interplay* [103] has drawn the attention of the scientific community, regulatory authorities, and drug developers [100]. Thus, *transporter phenotyping* is now also recognized as an important component of a complete understanding of the behavior of drugs and metabolites in the body.

1.6.5 Biological Aspects of Drug Metabolism

The activities of human drug-metabolizing enzymes are modulated by a number of factors and conditions (see Volume IV). As mentioned in Section 1.5.4, many drug-metabolizing enzymes are upregulated by chronic exposure of liver and other organs to xenobiotics, thereby promoting the metabolic CL of the foreign chemical. This upregulation occurs at the transcriptional level under the control of cytoplasmic or nuclear receptors which sense the presence of the xenobiotics inside cells and activate gene expression for a complement of enzymes and proteins related to drug metabolism [63] (chapter titled ***Transcriptional Regulation of Cytochrome P450 Genes***). Three important receptors for upregulation of drug-metabolizing enzymes are *AhR* (aryl hydrocarbon receptor), *CAR* (constitutive androstane receptor), and *PXR* (pregnane X receptor). The names of these receptors are not informative as to their activators or functions. AhR is a cytoplasmic receptor that is activated by some polycyclic aromatic compounds, such as benzo[*a*]pyrene, resulting in upregulation of CYPs 1A and 1B, GST (glutathione *S*-transferase), NQO1, and UGT1A enzymes (see Table 1.2 for enzyme abbreviations). This set of induced enzymes would be important for metabolic CL of benzo[*a*]pyrene and other aromatic compounds, so that continuous exposure of

a person to inducers such as benzo[*a*]pyrene would result in increased capacity of the person to clear such compounds. CAR is a nuclear receptor activated by phenobarbital and other drugs, resulting in upregulation of CYPs 2B and 3A, GST, and UGT1A enzymes. PXR is particularly important in clinical drug metabolism, since it is activated by many compounds (e.g., dexamethasone and rifampicin) and is the principal mechanism of upregulation of the important enzyme CYP3A4. Other enzymes/transporters upregulated by PXR include SULT1A, UGT1A, and MDR1. Since activation of these receptors can have profound effects on the clinical utility of a drug, *in vitro* assessment of the human induction profile is usually a screening requirement during the discovery process and is normally expected by regulatory authorities during registration of a new drug. If *in vitro* or animal data indicated the likelihood of enzyme induction, phase I clinical studies would be mounted to rigorously define the induction potential.

Physiological conditions such as menstruation and pregnancy affect drug metabolism, possibly necessitating dosage adjustments of medications taken during these times [104,105]. Similarly, drug-metabolizing enzymes and transporters are variably expressed during the stages of fetal development [106] (chapter titled ***Sex Differences in Drug Metabolism***). Enzyme levels continue to change through childhood, adulthood, and old age [107]. The enzymes of drug metabolism are even different in men and women, leading to gender differences in PKs [108]. Section 1.6.3 introduced the idea of genetic polymorphisms in many of the enzymes of drug metabolism, and it follows as a natural consequence that the corresponding alleles occur with higher frequency in some human populations (i.e., *pharmacogenetics*), making the nature and extent of drug metabolism variable across ethnic and genetic groups [109].

Disease states can effect an individual's ability to metabolize drugs, especially in inflammation and infection, where released cytokines can modulate levels of CYP enzymes [110]. Diet can increase or decrease the activities of drug-metabolizing enzymes and transporters, probably due to the effects of phytochemicals operating through several molecular mechanisms [111]. Even the time of day can make a difference in the ability of an individual to clear drugs, since enzyme expression and physiological processes such as blood flows are subject to *circadian rhythms* [112].

Finally, in light of the discussion above, it should be no surprise that the enzymes of animals are different from those of humans, both in amino acid sequences of the proteins and expression levels of the active enzymes (chapter titled ***Species Differences of Drug-Metabolizing Enzymes***). This has implications for human drug development because preclinical drug metabolism information is often used to help design and select drug candidates, but preclinical studies are performed by definition in animals, not humans. Thus, because the animal drug-metabolizing enzymes may have different activities and specificities from those of human, conclusions from animal studies are compromised. *In vitro* drug-metabolism studies with human hepatocytes avoid the problem of interspecies differences, but introduce the problem of *in vitro* to *in vivo* extrapolation. In response to this need for reliable *in vivo* human-relevant drug metabolism information to be available preclinically, various humanized transgenic mouse strains have been developed [113,114], but the reliable use of such models is still being explored.

1.7 THE CHEMICAL CHARACTERIZATION OF DRUG METABOLISM

1.7.1 ADME Studies

The acronym ADME stands for absorption, distribution, metabolism, and excretion. A human ADME study gives a complete description of how much of a drug candidate enters the body by a particular route of administration such as oral dosing, where the compound distributes within the body, what metabolites are formed and in what quantities, and what length of time is required for complete excretion of drug-related materials in feces and urine (see Volume II). A typical human ADME study is based on administration of a low dose of radiolabeled drug candidate (almost always carbon-14), followed by monitoring and quantitating radioactivity in various biofluids, tissues, and excreta to track drug and metabolites as they are absorbed, distributed, metabolized, and excreted.

In reality, of course, for the usual oral route of administration, we do not get complete information in any of these four areas. First, let us consider the “A” part of ADME. Radioactivity, consisting of parent drug and metabolites, recovered in the urine could only have come from intestinally absorbed parent drug and represents a minimum value for absorption. However, radioactivity recovered in the feces cannot be interpreted, since it contains biliary-secreted parent drug, metabolites, and unabsorbed parent drug. The summed radioactivity in urine and feces, then, does not provide an unambiguous estimate of the extent of absorption. Thus, an oral ADME study does not, by itself, necessarily give a reliable estimate of how much of an orally administered drug was intestinally absorbed. A parallel intravascular dose can provide a way to estimate the oral absorption, since the entire dose is known to have reached the systemic circulation in that case. By making the usually reasonable assumption of non-route-dependent elimination processes, we can proportionally scale the observed amounts of drug-related materials appearing in the urine to estimate the fraction of the oral dose that was actually absorbed (provided that the total urinary excretion of parent drug and metabolites was not trivial). Usually, however, an intravascular dose is not included in a human ADME study.

The situation is equally problematic for the “D” in ADME: distribution. In animal studies, it is possible to dissect a dosed animal and measure the radioactivity content of each organ as an indication of the extent and location of distribution of the parent drug in the body. However, this is impossible for a clinical study, so technically a human ADME study is really just an AME study. In most cases, we assume that the distribution of drug to human organs is similar to distribution to animal organs.

The “M” part of the ADME study is probably the most complete and reliable, but even here there may be serious deficiencies with some drugs. Radioactivity allows us to find and quantitate metabolites in blood, urine, feces, and other samples, and modern spectroscopic techniques make exact structure determination virtually assured. However, with some drugs, a fraction of the radioactivity may be retained in the body for a prolonged period, perhaps as covalently attached drug residues from reactive metabolites. In these cases, radioactivity only appears in the excreta after the biological target of the covalent attachment has been broken down by degradation processes. Thus, information about the chemical identity of the reactive metabolite is lost. Furthermore, metabolites recovered in feces may have been produced from unabsorbed parent drug

or further transformed by intestinal microflora, obscuring the origin of these metabolites. Nonetheless, despite these deficiencies, human ADME studies, especially when supplemented by other studies such as animal ADME, human PKs, and enzyme phenotyping, provide the best overall picture of the handling of the drug by the human body. This is the reason that radiolabeled ADME studies are routinely required by regulatory authorities for registrational and product labeling purposes. For example, a recently published human ADME study of [^{14}C]-prasugrel identified over three dozen metabolites, which were rationalized by a scheme of metabolic pathways that showed the process for formation of the metabolite mainly responsible for the pharmacological activity. Exhaustive collection of urine and feces showed that $\sim 95\%$ of the drug and metabolites was excreted within 10 days. Since about 70% was recovered in the urine, intestinal absorption of the oral dose of prasugrel must have been at least 70%. [28].

1.7.2 Metabolite Structure Elucidation

Characterization of the exact chemical structure of the major metabolites of a drug candidate is the foundation for understanding human drug disposition. The chemical structure may provide clues to the possible pharmacological or toxicological properties of the metabolite, and these can be investigated by independent synthesis because the structure is known. In most cases, the structure of each metabolite tells which type of enzyme accomplished the metabolic transformation, as can be demonstrated by comparison of the reactions in Table 1.1 to the enzymes in Table 1.2. It is relatively straightforward from that point to determine which particular enzyme of the family for that type of enzyme was the actual catalyst for the chemical transformation. Once the particular enzyme in the family is identified, then a set of characteristics for that drug immediately become apparent, such as which drugs will likely show interactions, whether polymorphic kinetics are likely to be observed, and whether induction is likely to be a clinical issue. Therefore, rigorous determination of metabolite chemical structure is absolutely essential when characterizing a new clinical candidate.

Metabolite structure elucidation requires the most advanced spectroscopic techniques (Volume V). This is because most such structure determination is accomplished with nano- or microgram quantities of metabolite in a chromatographic mobile phase matrix or with a somewhat impure sample when actual isolation must be accomplished. Chemical reactions are seldom used as a means of determining metabolite structures except in special cases of derivatization to facilitate chromatography or spectroscopy. The workhorse analytical method for metabolite separation and detection is LC combined with *radiometry* [115]. Structural identification of metabolites is mainly accomplished with *mass spectrometry* (MS) coupled with LC, so that metabolites are separated and introduced one-by-one into the inlet of the mass spectrometer (LC-MS). Several types are available depending on the exact information sought [116]. When necessary, *nuclear magnetic resonance spectroscopy* (NMR) is a powerful adjunct to MS that can typically provide structural information which is difficult or impossible to obtain from MS alone, such as the exact position of a hydroxyl group introduced by a CYP enzyme [117].

Since enzymes are involved in almost all metabolic transformations, we typically expect to see stereoselectivity of the metabolism when the parent drug or the metabolite contains one or more stereogenic centers [118]. The significance of *stereochemistry* in metabolism comprises four distinct phenomena. First, a drug which has a stereogenic

center (e.g., *R,S*-warfarin) may show differential rates, metabolic pathways and enzyme preference between the *R*- and *S*-stereoisomers [119]. Second, a drug lacking a stereogenic center may be metabolized in such a manner that a chiral center is introduced, and the enantiomeric metabolites are unlikely to be produced in equal proportions. For example, the achiral drug risperidone is hydroxylated by CYP enzymes to produce both *R*- and *S*-9-hydroxyrisperidone metabolites [119]. Third, a drug containing a stereogenic center may undergo metabolism that eliminates chirality at that carbon atom. For example, the stereogenic secondary alcohol functional group in ezetimibe is oxidized to an achiral ketone (see Fig. 1.13 in Table 1.1). Finally, a drug containing a stereogenic center may undergo *stereochemical inversion*. For example, chiral “profen” drugs such as ibuprofen are metabolically inverted such that the pharmacologically inactive *R*-isomers are converted to the active *S*-isomers [120,121]. In this last example, the subtle change of structure, although important for fully understanding the activity of the drug, would go undetected by ordinary achiral means of chromatography and structural analysis. Therefore, inversion of configuration represents a type of metabolism that must be specifically investigated by chiral methods on the “parent”-drug chromatographic peak.

Since the exact nature of the metabolic reactions observed to occur with a particular drug determines which enzymes are involved and whether active, toxic, or reactive metabolites are generated, a natural exercise is to try to predict preclinically which reactions will be most important for a given drug candidate in humans. Much effort has been devoted to this endeavor and considerable progress has been made, but these computational predictions have limitations and are not yet completely reliable [122]. Nonetheless, predictive software has been documented to be of value in avoidance of certain metabolic liabilities during the design of new drug candidates [123].

1.7.3 Quantitation of Extent of Metabolism

The fraction of the absorbed dose that is metabolized before excretion is called the *extent of metabolism*. Although the fraction of the total drug-related material represented by metabolites in blood is frequently equated with the extent of metabolism, this is clearly not correct, since the concentrations of metabolites in blood compared to the concentration of parent drug are determined not only by the extent of metabolism but also by the PK CLs and volumes of distribution of the metabolites relative to the parent drug. Correct assessment of the extent of metabolism involves summing up the amounts of all metabolites excreted in urine and feces and expressing as a percentage of the administered dose. Since most marketed drugs are orally administered, then when absorption from the intestinal tract is incomplete, unabsorbed parent drug is subject to bacterial metabolism because of the microorganisms in the large intestine. It is often difficult to distinguish whether certain metabolic reactions such as hydrolysis and reduction occurred systemically or in the intestinal lumen. A related ambiguity occurs when a reversible type of metabolism such as glucuronidation or *N*-oxidation occurs in the liver followed by secretion into the intestine through the bile. Bacterial enzymes often can hydrolyze glucuronides and reduce *N*-oxides back to parent drug, which would be recovered in the feces. In that case, we would underestimate the extent of metabolism by assuming that the parent drug recovered in feces had not been metabolized. Sampling of bile in animal studies can alert us to the probability

of reversible metabolites in bile. However, while it is possible to obtain human bile samples as well, this is not routinely done in the absence of a reason more compelling than just detection of reversible metabolism. For these reasons, it may be difficult to reliably assess the true extent of human metabolism in certain cases.

1.7.4 Elimination of Drug-Related Materials from the Body

The “E” of the ADME study is measured as the sum of radioactivity recovered in both urine and feces after exhaustive collection, typically two weeks for an average drug. Obviously, drugs exhibiting a long PK half-life might require more than two weeks to be completely excreted. In other cases, incomplete recovery of radioactivity may indicate that metabolites are retained for a prolonged period, though it might also have just been the result of losses during collection of urine and feces. A reasonable expectation for total recovery of excreta over two weeks from human subjects is about 80–90%, so that recoveries which are significantly lower than that may indicate prolonged retention of metabolites, possibly as drug residues covalently bound to tissues [124]. In animal ADME studies, the residual radioactivity can be measured in carcass to resolve the ambiguity of long-retained metabolites versus simple losses, and this information can be helpful in understanding a human mass balance study with low recovery. A drug that clearly accumulates in the body, as either parent drug or metabolites, is a cause for concern and a possible reason for discontinuation of further clinical development.

1.8 CONCLUSION

Drug metabolism is nominally a chemical event, and the purely chemical aspects of the study of the process, such as separation and rigorous structural identification of the metabolites, require the most advanced chromatographic and spectroscopic chemical techniques. The chemical outcome of drug metabolism is important because the metabolites produced may have pharmacological or toxicological properties of their own, independent of those of the parent drug. However, drug metabolism arises from a complex set of biological phenomena that is only manifest at the end as a chemical transformation of a drug molecule. The biological aspects are equally important as the chemical aspects in contributing to the overall clinical profile of a drug. These biological aspects include the rate of enzymatic conversion of drug to metabolite, which largely determines the biological half-life, the particular enzymes that are responsible for the conversion, because some enzymes are subject to genetic polymorphism, and the regulation of those enzymes and their associated cofactors. Metabolism-based drug–drug interactions, which can seriously compromise the clinical usefulness of a drug, represent a higher-order feature of the biological side of drug metabolism. These clinical consequences of drug metabolism are the reasons that regulatory authorities require a complete description of the metabolic fate of a new drug candidate. Furthermore, the desire to design “druglike” molecules to minimize metabolism-related difficulties in clinical development explains why drug discovery organizations expend considerable effort to characterize the metabolism of research molecules before selecting the best one to enter clinical development.

ABBREVIATIONS

AcSCoA	Acetyl Coenzyme A
AMP	Adenosine Monophosphate
ADP	Adenosine Diphosphate
ATP	Adenosine Triphosphate
CoASH	Coenzyme A
CPR	Cytochrome P450 Reductase
FAD	Flavin Adenine Dinucleotide
FMN	Flavin Mononucleotide
GSH	Reduced Glutathione
NAD ⁺	Nicotinamide Adenine Dinucleotide
NADH	Reduced Nicotinamide Adenine Dinucleotide
NADP ⁺	Nicotinamide Adenine Dinucleotide Phosphate
NADPH	Reduced Nicotinamide Adenine Dinucleotide Phosphate
PAPS	Phosphoadenosine Phosphosulfate
SAM	S-Adenosine-L-Methionine
UDP	Uridine Diphosphate
UDPGA	Uridine Diphosphate Glucuronic Acid

2.1 SUMMARY

Drug metabolism is the body's inherent ability to remove foreign compounds (xenobiotics) that have either intentionally or unintentionally made their way to the systemic circulation or organs within the body. Understanding the metabolism of newly developed drugs is paramount because of the central role metabolism plays in unraveling the possible toxicity or developability of new drug candidates. For example, the rate of drug metabolism in part determines the bioavailability, clearance, and half-life of a drug, and together, these parameters define how much drug (dose) and how often the drug needs to be dosed. Both these factors (dose size and frequency) can be significant hurdles to new drugs especially if the dose or dosing frequency is too high, making the drug unmanageable to develop or market. Also, metabolism is often considered a detoxification pathway by which the molecules are chemically modified to make them more polar and easily excreted from the body, eventually rendering them pharmacologically inactive. However, there are numerous examples where metabolism renders a compound less soluble (N-methylation reactions), pharmacologically active, or toxic. Therefore, it is always important to understand the full set of metabolic reactions and enzyme involved in the metabolism of a compound in both preclinical models (pharmacokinetic, pharmacological, and toxicological) as well as in human to avoid any unnecessary complications or failures in drug development.

Drug metabolism occurs everywhere within the body to differing extents; however, metabolism occurs predominately in those organs involved in elimination (e.g., kidneys and liver) and those organs to which the drug is first exposed [e.g., gastrointestinal

tract (GI) and liver]. The most common drug-metabolizing organs or compartments are liver, GI tract, kidney, plasma, brain, skin, lung, and nasal mucosa with the liver and GI tract being the most abundant in enzyme level and capacity [1]. Often overlooked are another set of drug-metabolizing enzymes found in the GI tract, which being the microflora that can metabolize foreign compounds as they travel along the lower GI [2–4]. Typically, these microorganisms act through hydrolysis and reductive metabolic pathways, given the environment in the lower GI tract. Therefore, metabolites found in feces often need to be considered as being derived from metabolic reactions of the host organism as well as the microflora.

Clearly, metabolism can occur in many sites and organs within the body, but often specific cell types within the organ are responsible for the majority of metabolic reactions, such as the hepatocyte in the liver and the enterocytes within the intestine.

Focusing even further down, there are numerous subcellular organelles within each organ that contain significant quantities of drug-metabolizing enzymes that participate in the metabolism of xenobiotics, such as the microsomal fraction (derived from the endoplasmic reticulum), cytosol, and mitochondria. The following section describes various *in vitro* and *in vivo* models that are often employed throughout drug discovery and development, as well as the purpose each model system serves to provide valuable information to elucidate the metabolic disposition of new and existing drug molecules. The information contained within will be based on the authors own experiences and numerous seminal publications in the area of *in vitro* and *in vivo* drug metabolism [1,5,6].

2.2 IN VITRO MODELS OF DRUG METABOLISM

In vitro models of drug-metabolism range from single enzymes to whole organs. The models can be categorized into two distinct groups: (i) models that contain intact cells, such as whole organ, slices, or cells and (ii) subcellular fractions. Each model system has its own utility in the study of drug metabolism in either drug discovery and/or development along with a set of advantages and disadvantages, all of which are highlighted in the following sections. General procedures are provided for the isolation and characterization of the most commonly employed *in vitro* model systems, such as microsomes, cytosol, and hepatocytes, which are described in detail by Guengerich and LeCluyse, respectively [7,8].

2.2.1 Individual Enzymes

The single or individual enzyme system is a useful tool to study enzymatic activity in a controlled environment of enzyme content, buffer, and cofactors all of which can be easily manipulated. Generally, the total protein content of such incubations is extremely low and reduces the effects of nonspecific binding, which can be a benefit as opposed to using large quantities of enzyme mixtures to obtain the same amount of enzyme activity. Often, the specific content or quantity of enzyme is known and as such the enzyme activity or turnover can be directly measured as a function of “nanomoles of enzyme” as opposed to the generic measure of “milligrams of protein” or “number of cells.”

Enzymes were initially isolated from a tissue, which is a labor-intensive procedure, leading to significant loss of enzyme content (activity) with each successive isolation

TABLE 2.1 Applications of *In Vitro* Drug Metabolism Models

Bioreactor	XXX	XXX	XX	X	X

XXX, commonly used; XX, sometimes used; X, rarely used.

step. Few enzymes today are isolated by this method, however, some are still easy and cost effective to isolate in this manner, such as β -glucuronidase from snails and alkaline phosphatase from bovine liver or intestine. More commonly, enzymes are individually expressed as recombinant enzymes through cDNA-directed expression systems in a variety of host cell lines (mammalian, bacterial, insect, and yeast) and are commercially available from multiple vendors [9–12].

The most commonly employed single-enzyme family is the cytochrome P450 (CYP) family of isozymes, which have been used to evaluate metabolic stability, human hepatic clearance, drug–drug interaction potential (inhibition), reaction phenotyping (i.e., identification of enzymes involved in metabolism of a drug candidate), the effect of allelic variants of drug-metabolizing enzymes on metabolism and elimination, and the potential to undergo bioactivation or covalent binding; serve as bioreactors to generate significant quantities of metabolites for identification purposes; and as a tool to directly study enzyme structure and function [10,12–16]. Table 2.1 illustrates the utility of single-enzyme systems across a range of drug-metabolism studies conducted throughout drug discovery and development. Many of the other individually expressed drug-metabolizing enzymes (e.g., glucuronyltransferases, sulfotransferases (STs), epoxide hydrolases, flavin monooxygenases (FMOs), glutathione *S*-transferases, and *N*-acetyltransferases [11,17]) can also be used for the aforementioned studies; however, they are used less often than the CYP enzymes because of the propensity of most drugs to be substrates of one or more of the CYP isoforms.

In some situations, the results from single-enzyme systems may not always mimic other *in vitro* models or *in vivo*. For example, if the overall metabolism is derived from multiple individual enzymes then the activity from a single enzyme will not properly reflect the overall metabolic clearance. Also, there are numerous examples where mechanism-based inactivation has been observed in recombinant enzyme preparations but not in other *in vitro* models such as liver microsomes likely because of more efficient formation of reactive metabolites in the focused individual enzyme system [18]. In general, the single-enzyme system will tend to overemphasize the importance or potency of metabolic reactions, nonetheless, they are extremely useful in breaking down complex metabolic pathways into individual pathways or enzymes.

Figure 2.1 Isolation procedure for liver subcellular fractions: S9 fraction, cytosol, and microsomes.

2.2.2 Subcellular Fractions

By use of tissue homogenization and differential centrifugation, it has become possible to obtain various subcellular fractions such as S9, cytosol, and microsomes. Depending on the tissue, either the entire organ or portions of the organ are more appropriate for subcellular isolations. For example, when preparing liver subcellular fractions, the entire liver is used; however, for intestinal or kidney microsomes, generally only certain cell types or tissue layers containing the enzyme(s) of interest are used to prepare subcellular fractions (e.g., enterocytes from the intestine).

Figure 2.1 outlines the general procedure for the isolation of liver subcellular fractions and the procedures for the most common drug-metabolizing organs, liver, and intestine are described in detail in the Refs 8 and 19. Briefly, the procedure begins with cooling the excised liver as quickly as possible to 4°C with buffer and all remaining buffers and steps are conducted at 4°C to ensure the best possible enzyme stability. The liver is then homogenized in four volumes of ice cold buffer and centrifuged at low speed (1000×g) to remove unbroken cells, cellular debris, and nuclei. The supernatant from this step is then centrifuged at 10,000×g to further pellet unwanted organelles such as mitochondria and lysosomes (note this pellet may be used for other drug-metabolism-related experiments). The supernatant from this step is the S9 fraction and is centrifuged at 100,000×g to yield the supernatant (cytosolic fraction) and the microsomes (pellet of endoplasmic reticulum). These subcellular fractions can be stored frozen at −80°C for long periods of time (years) and as such they serve as a convenient source of enzyme for drug-metabolism studies and have become widely available commercially. Owing to their ready availability, subcellular fractions are used in a variety of drug-metabolism- and toxicity-related studies [11–13,20–22].

Most drug-metabolizing enzymes are located in the cytosolic and microsomal fractions as outlined in Table 2.2, although others can be found in lysosomes, peroxisomes,

and mitochondria. The predominate subcellular fraction for evaluating drug metabolism is the microsomal fraction. The microsomal fraction containing the smooth endoplasmic reticulum is the most commonly employed *in vitro* model because most drugs are metabolized by the cytochrome P450s or by glucuronidation, both of which are found in the microsomal fraction. Table 2.1 illustrates how the microsomal model is used in nearly every evaluation except enzyme induction. The cytosolic fraction is used less frequently, however, when the major enzyme involved in metabolism or inhibition (e.g., sulfotransferase or aldehyde oxidase (AO)) of a particular drug is located in the cytosol then this model becomes extremely useful. The S9 fraction also has utility when complex metabolic pathway need to be studied, for example, when multiple different metabolic pathways are involved, such as hydroxylation by CYP followed by sulfation or carbonyl reduction followed by CYP-mediated oxidation and then some form of conjugation. Often when the metabolic pathways become too complex, it is better to use a more appropriate and relevant system such as the hepatocyte model, which is discussed in the following section.

2.2.3 Cellular Systems

Cellular systems can be categorized into two general groups: primary cells isolated from tissues and immortalized cell lines. Both have utility in assessing a variety of drug-metabolism functions; however, the primary cells tend to be employed more often in routine characterization, whereas immortalized cell lines are often used in early drug discovery and in higher throughput assays [23,24]. Primary animal or human hepatocytes isolated from liver tissue is the predominate cell-based model to evaluate drug metabolism (Table 2.1) [23,25]. Like the aforementioned subcellular fractions, hepatocytes can also be cryopreserved and stored for long periods of time, which makes them highly useful for routine or even high throughput assays to assess metabolic stability, metabolite identification, induction, or cytotoxicity. The most common method of isolating hepatocytes from all species is the two-step perfusion method that utilizes a calcium-free buffer in the first step followed by a buffer containing the enzyme collagenase [7,26]. The isolation of hepatocytes from liver tissue is not extremely challenging; however, time and practice are necessary to obtain high quality cells especially from animals other than the rat. Depending on the study type, the hepatocytes can be used as a cell suspension (generally only for 2–3 h) or in cell culture (for several days) [25]. Hepatocytes in suspension represent a fully functional unit of drug metabolism from the liver containing normal concentrations of enzymes and cofactors with the ability to perform complex and multistep metabolic reactions. Therefore, hepatocytes in suspension are commonly used to determine metabolic stability, predict human metabolic clearance, and compare metabolic pathways or metabolite identification across multiple species [22,25,27–30]. Less often, but still of value are studies using hepatocyte suspensions for assessment of drug inhibition, reaction phenotyping, bioreactors for metabolite formation, and cytotoxicity measurements. Unfortunately, when in suspension, the hepatocytes are no longer attached to an extracellular matrix or to one another, which is an inappropriate environment for the cells. Hence, the viability of the cells will begin to decline somewhere around 2–3 h in suspension limiting the length of incubation time and, therefore, the degree or extent of metabolism. Hepatocytes in culture will survive for several days or even weeks because of the artificial environment created in culture with an extracellular matrix and cell-to-cell contact. Hepatocytes in culture

are predominately used to assess enzyme induction (transcriptional activation) and the potential for drug–drug interactions or cytotoxicity [22,26,31,32]. Unfortunately, even in culture, the hepatocytes will begin to dedifferentiate and the phenotypic properties of the cells may start to change within 24–48 h in culture. Most important of these changes are those of the CYP enzymes, which in general will decrease with time in culture; however, some CYPs have been shown to increase and others to decrease and then increase with culture time. Owing to these ever changing levels of the major drug-metabolizing enzymes, many of the other drug-metabolism-related studies are not suited for this model. However, modern advances in cell culturing techniques such as microfluidic flow systems, micropatterned hepatocyte coculture systems, and different three-dimensional cultures such as spheroids have made significant advances in improving the stability and longevity of drug-metabolizing enzymes in culture [33–35].

Immortalized cells are cells that can grow and divide indefinitely under optimal conditions, hence they are attractive as a cellular model, which can provide an inexpensive supply of cells that are phenotypically stable. A variety of cell lines are currently available and used in the assessment of drug metabolism, such as HepG2, Fa2N4, BC2, and HepaRG [23,24,36,37]. Each cell line has a particular or general utility in drug-metabolism studies because each cell line is unique in the expression of drug-metabolizing enzymes (oxidative enzymes such as CYPs or conjugation enzymes), transcription factors (e.g., pregnane X receptor or constitutive androstane receptor), or drug transporters. Therefore, when deciding which cell line to employ, one must first consider the type of evaluation or question is being asked, for example, is the experiment designed to assess metabolite formation/identification or enzyme induction. Although immortalized cell lines are readily available and useful for many applications, there is no single cell line that recapitulates the genotype and phenotype of a primary human hepatocyte and therefore cannot be used as a replacement for primary hepatocytes but can be used in higher throughput models as primary or secondary screens.

2.2.4 Organ Slices

Tissue slices have been prepared from multiple organs, predominately the liver and also intestine, kidney, brain, and lung [11,38,39]. Tissues such as the liver and heart are rigid enough to be sliced directly; however, soft tissues such as the intestine and lung are generally imbedded in agarose and then sliced [39]. Tissue slices, in contrast to the aforementioned *in vitro* models, represent a higher level of structural integrity and architecture containing all of the organ cell types, cellular attachments to basement membranes, and cell-to-cell contacts [40,41]. Liver slices, first noted in the literature in the 1920s and 1930s, are one of the earliest *in vitro* models to evaluate metabolism, pharmacology, and toxicology [42,43]. The early slices were extremely crude and slice thickness was not reproducible, however, they did demonstrate metabolic activity. With the advent of specialized slicing, such as the Krumdieck and Brendel tissue slicers, tissue slice thickness became more reproducible and slices were prepared with minimal tissue damage. Typical liver slices range in thickness from about 200 to 300 μm and generally maintain metabolic function for 24–96 h under appropriate culture conditions. Today, the technology of tissue slicers continues to improve [44], as do the culture conditions, which have moved in the direction of fluidic perfusion techniques [45] as

compared to the earlier roller incubators or multiwell plates, which bathed the tissue slice in media in an atmosphere of oxygen and carbon dioxide.

Tissue slices have many of the same applications as hepatocytes or other cell-based models; however, the advantage of intercellular connections between different cell types within the slice can provide a greater level of cellular communication and function especially in cases where multiple cell types are necessary for complex metabolic or toxicological pathways. As with the cellular models, the enzymatic activity (e.g., CYPs) within the slice begins to decline shortly after being placed in culture. Early applications of tissue slices were the assessment of toxicology and pharmacology, however, drug-metabolism studies such as metabolite identification, species comparisons, and enzyme induction have been prominently noted in the literature [39,41,46–48]. A somewhat controversial application of liver slices is that to predicting metabolic clearance. Concerns have been noted that the slice thickness acts as a diffusional barrier for access of drug and oxygen to the interior of the slice. With some drugs, the rate of metabolism may not be entirely based on metabolic reactions but on the rate of drug diffusion throughout the slice, hence the rate of determination may be compromised by diffusion or transport. Owing to this uncertainty, slices have not been used routinely as a model to assess clearance, however, they do recapitulate the rank order of metabolic rates, just not the values calculated from *in vivo* or other *in vitro* methods such as hepatocytes [40,41].

Tissue slices are not amenable to cryopreservation, therefore, experiments must be conducted on freshly isolated and sliced organs that makes tissue slices not as useful for routine studies, especially when slices are required from species other than the rat. Many of the same drug-metabolism studies that are conducted in liver slices can also be performed using hepatocytes, which can be cryopreserved making the hepatocyte model a more routine model for most applications. An advantage of tissue slices, similar to hepatocytes, is the ability to reproduce complex metabolic processes where more than one metabolic reaction occurs on the molecule (oxidation in combination with conjugation) or when more than a single cell type is required for a reaction or biochemical process.

2.2.5 Organ Perfusion

Organ perfusion experiments can be conducted either *ex vivo* or *in situ*, but it is not technically an *in vitro* method; however, it is covered in this section to distinguish the technique from live intact animal studies. Perfusions have been conducted on many organs such as the liver, heart, lung, kidney, brain, intestine, intestine–liver preparations, and pancreas [49–51]. There are several key references that outline the procedures for organ isolation and perfusion for both liver and intestine [50,52,53]. Owing to the size of these organs, most organ perfusions are generally limited to smaller animals such as rats and rabbits. Organ perfusions, such as the liver or intestine, offer several advantages over other techniques in that the delivery and sampling of the drug under investigation can be by physiological routes, such as the portal vein, bile duct, or intestine. In addition, the concentration of drug, buffer, and rate of drug delivery can all be easily manipulated during the experiment and tailored to the needs of the investigator. A significant disadvantage of the isolated perfused organ method is that only a single organ (i.e., single experiment) can be conducted per animal, which is in contrast to all of the previously described methods.

Liver perfusions or the combination of intestine–liver perfusions provide a good model to assess first-pass metabolism as well as the combination of drug-metabolizing enzymes in conjunction with transporter-mediated efflux (both are mechanisms of drug clearance from the liver). For example, Xu *et al.* [49] used the intestine–liver dual perfusion model to evaluate the first-pass metabolism of salicylamide, while other researchers have used the liver perfusion model as a means to study the interplay between metabolism and transport-mediated elimination or inhibition of transport-mediated elimination [54,55]. There is no doubt that the organ perfusion model replicates many of the delivery, sampling, and connectivities between enzymes and transporters that other *in vitro* models cannot duplicate, making it a powerful tool to study these combinatorial drug disposition and metabolism effects.

2.3 IN VIVO MODELS OF DRUG METABOLISM

In vitro models of drug metabolism are extremely useful to study specific reactions, mechanisms, or structure–activity relationships, however, *in vivo* systems are required to understand additional factors that may contribute to the type of metabolism, rate of metabolism, or other elimination pathways in the overall disposition/exposure of a drug or metabolites. For example, extrahepatic metabolism, protein-binding effects, first-pass metabolism, or the effects of a disease state on drug-metabolizing enzymes [56]. In addition, when metabolites are present in high concentrations, they may need to be quantitated as they may contribute to target pharmacology or off-target liabilities [57,58]. *in vivo* drug-metabolism studies are categorized as preclinical (animal) and clinical (human) studies. In broad terms, the purpose of these studies is to assess the metabolic profile of a drug across animal species and eventually humans. By identifying the *in vivo* metabolites, correlations can be made to the *in vitro* metabolic profiles, assess the possibility of active or toxic metabolites, and determine the elimination pathways of parent drug and metabolites.

2.3.1 Preclinical Animal Studies

The most commonly sampled biological matrices from *in vivo* drug-metabolism studies include plasma, urine, and bile, as well as feces in some situations. Plasma and urine are readily sampled matrices, however, bile collection requires surgically altered animals that have been bile duct cannulated [56]. In such studies, plasma, urine, bile, and feces can be examined for parent drug and metabolites [59,60]. Many drugs are eliminated in bile as parent drug and especially as metabolites. Without the use of bile duct cannulated animals (e.g., intact animals), it would be difficult to assess the overall routes of drug or metabolite elimination, metabolic pathways, or amount of metabolism because of the elimination of bile into the GI tract, which eventually appears in feces. As mentioned previously, identification of parent drug or metabolites is challenging from feces because of the microflora in the GI tract, which can further metabolize compounds or alter metabolic profiles.

In early drug discovery, metabolite identification is conducted with “cold” or non-radiolabeled drug, and it can often be difficult to obtain a full metabolic profile along with metabolite concentrations. However, in late drug discovery or drug development,

radiolabeled compounds (carbon-14 or tritium) are employed as substrates and metabolite identification is more straightforward as even minor metabolites can be observed and quantitated with respect to one another and parent drug. In rarer instances, stable labeled drugs can aid in elucidating the pharmacokinetics, disposition, or metabolism of a drug from *in vivo* studies as well as address mechanistic questions from *in vitro* models [61].

An essential *in vivo* animal study is the mass balance study conducted in rodent and nonrodent species. In this study, animals are dosed either orally or intravenously (or both) with a radiolabeled drug and radioactivity is measured from bile, urine, feces, exhaled $^{14}\text{CO}_2$, animal carcasses, and cage washings [62]. The purpose of this study is to (i) determine the major elimination pathways of drug and drug-related material; (ii) determine the total recovery of radiolabeled material (what goes in should come out); and (iii) conduct metabolic profiling from the various matrices collected to verify that the human metabolites generated are the same as those formed in sufficient quantities in the toxicology models. Sometimes, specific tissues may be collected at various time points for determination of total radioactivity or metabolites to determine tissue distribution (e.g., brain, liver, adrenal). In general, good recovery of radioactivity after a sufficiently long collection period would be 90%, 85%, and 80% for rat, dog, and human studies, respectively [63]. Generally, monkey studies are more challenging and lead to somewhat less recovery of total radioactivity due to issues with incomplete dosing and sample collection.

Additional studies related to drug metabolism in preclinical species can include regulation of drug-metabolizing enzymes, understanding the mechanism of low systemic exposure, and determination of hepatic extraction. Enzyme induction in animals can be assessed by dosing animals for multiple days (generally one to two weeks) after which the liver is removed and the RNA expression or enzyme activity of various drug-metabolizing enzymes (typically CYP1A, 2B, and 3A) are measured. In some situations, the administration of specific or global enzyme inhibitors can help elucidate the enzymes involved in metabolism or determine the mechanism of low exposure. For example, the global CYP450 inhibitor 1-aminobenzotriazole (ABT) can be administered to rats to address (i) gut versus liver contributions to first-pass metabolism [64] or (ii) low systemic exposure due to poor absorption or high first-pass metabolism [65]. Determination of hepatic extraction can be accomplished by infusing the drug via the portal vein and measuring systemic parent drug and/or metabolites [56]. This is a reasonable model when conducted in rats; however, in higher animal species such as the dog or monkey, it generally requires implantation of vascular access ports that lead to the portal vein [65].

2.3.2 Species Differences in Drug Metabolism

Species differences in drug metabolism are common and frequently complicate the extrapolation of metabolite data from preclinical animal models (in particular, pharmacology and toxicology species where active or toxic metabolites, respectively, can have dramatic effects) to the human metabolic profile [66]. Species differences in drug metabolism are generally related to (i) lack of a specific enzyme either in humans or animals; (ii) similar enzyme orthologs between species, which form different metabolite products; or (iii) greatly reduced activity of particular enzymes in preclinical species

that may predominate in humans, for example, AO [66]. Many common species differences in drug metabolism is described in the chapter titled *Sex Differences in Drug Metabolism* of this volume. Some of the most common species difference relate to the CYP family of enzymes [66,67], metabolites formed by N-acetylation where dogs lack this particular enzyme [68,69], or the formation of quaternary *N*-glucuronides where this particular conjugate is typically only formed in humans and monkeys but not in standard preclinical species [70]. For example, the anticonvulsant lamotrigine is formed in humans and monkeys as a major metabolite; however, this same metabolite is not found in standard preclinical species (rat and dog). Interestingly, the quaternary *N*-glucuronide of lamotrigine is the major metabolite formed in guinea pigs [71,72]. Finally, a number of drugs have the ability to induce various sets of drug-metabolizing enzymes in the liver and various other tissues such as the intestine. The major mechanism by which drug-metabolizing enzymes are induced are via transcriptional activation through nuclear hormone receptors or transcription factors. These receptors have been well characterized and shown to have significant species differences with regard to ligand binding and ultimately induction of drug-metabolizing enzymes. Therefore, observation of enzyme induction in any single species has little association to induction in other species, in particular, human enzyme induction [31,32,67,73].

2.3.3 Transgenic and Chimeric Mouse Models

The involvement of a single enzyme, transporter, transcription factor, or a small set of these proteins that are involved in metabolism, bioactivation, disposition, gene expression, or toxicity of a drug can be evaluated through the use of genetically modified knockout or humanized mouse models [74–78]. A large number of knockout mouse models (drug-metabolizing enzymes, drug transporters, and transcription factors involved in the regulation of enzymes and transporters) have been generated through genetic manipulation, Tables 2.3–2.5 [78–84]. The knockout mouse model is extremely useful in understanding the function of a single gene (protein) or the function of multiple enzymes all of which are controlled from a single gene. For example, cytochrome P450 reductase is an obligatory enzyme involved in all cytochrome P450 oxidations, and a cytochrome P450 reductase knockout mouse would be devoid of significant P450-mediated oxidation. The P450 reductase mouse (also known as POR KO or Cpr KO) was useful in distinguishing between cytochrome P450-mediated and FMO-mediated N-oxidation of the antitumor agent C-1311 [85]. When C-1311 was dosed to reductase knockout mice, there were only limited changes to the metabolism of the parent drug and formation of the *N*-oxide was unchanged. These data helped support the presumption that drug–drug interactions due to changes in cytochrome P450 enzyme activity would be greatly reduced when employing this antitumor agent because the drug interacted with FMO and not P450.

Humanized mouse models are created by insertion of a human gene(s) into the mouse genome, or more often, by deletion of the mouse orthologous gene and insertion of the human gene (Tables 2.3–2.5). This second method is generally preferred as it eliminates the confounding factors involved with having both human and animal orthologous genes present and functional at the same time. For example, the transgenic mice expressing the human UGT1A (1–9) locus demonstrated expression of the nine

TABLE 2.2 Subcellular Location of Drug-Metabolizing Enzymes

Reaction	Enzyme	Location
Oxidation	Cytochrome P450 (CYP)	Microsomes
	Flavin monooxygenase (FMO)	Microsomes
	Aldehyde oxidase (AO)	Cytosol
	Xanthine oxidase (XO)	Cytosol
	Alcohol dehydrogenase	Cytosol
	Aldehyde dehydrogenase	Mitochondria and cytosol
	Monoamine oxidase (MAO)	Mitochondria
	Dihydrodiol dehydrogenase	Cytosol
	β -Oxidation	Mitochondria and peroxisomes
Hydrolysis	Carboxylesterases (esterase/amidase)	Microsomes, cytosol, lysosomes, plasma, blood
	Epoxide hydrolase	Microsomes and cytosol
	Peptidase	Blood and lysosomes
Reduction	Sulfoxide/disulfide reductase	Cytosol
	Quinone reductase	Microsomes and cytosol
	Reductive dehalogenation	Microsomes
	Azo and nitro reductase	Microsomes, cytosol, microflora
	Carbonyl reductase	Microsomes, cytosol, blood
Conjugation	Glucuronide conjugation	Microsomes
	Sulfate conjugation	Cytosol
	Methyltransferase	Microsomes, cytosol, blood
	<i>N</i> -Acetyltransferase	Cytosol and mitochondria
	Glutathione conjugation	Microsomes and cytosol
	Amino acid conjugation	Microsomes and mitochondria

human UGT1A genes in a similar pattern as observed in human tissue. Senekeo-Effenberger *et al.* [86] used this transgenic model to demonstrate that human UGT1A1, 3, 4, and 6 were targets of the peroxisome proliferator-activated receptor alpha (PPAR) and that with an appropriate PPAR ligand (WY-14643) dosed to transgenic mice, and these human genes were induced in the liver, GI, or kidney.

Along with the advantages of employing an *in vivo* knockout or humanized model, come a few precautionary notes. There are genetic manipulations that can precipitate inappropriate expression of the human transgene or endogenous mouse genes. For example, the expression of a human gene to evaluate metabolism should be expressed at levels similar to those found *in vivo* in humans. Often the expression of human transgenes can be lower than those found *in vivo* or may be expressed in the wrong tissues. This can be due to a lack of necessary regulatory sites in promoter regions or a lack of cellular components such as coactivators/cofactors from the mouse that do not interact properly with human promoter/gene complexes. In addition, the deletion of a mouse gene (knockout) or insertion of a human gene (humanized) can lead to changes (up or down) in the expression of other mouse genes because of changes in endogenous

metabolic pathways caused by the gene deletion/insertion. Nonetheless, these models offer the advantage of studying a human drug-metabolizing gene (function) or transcription factor in an *in vivo* setting (mouse), thereby avoiding many of the limitations imposed by *in vitro* systems that cannot appropriately recapitulate such affects as protein binding, liver uptake, or the time course of drug/metabolite exposures. The use of these mouse models have significantly increased our knowledge of the expression and function of many enzymes and proteins involved in drug metabolism. The generation of additional knockout or humanized mouse models beyond those currently available will provide tools, much like the plethora of *in vitro* tools, to routinely study drug metabolism in greater detail using an *in vivo* approach.

The chimeric mouse model is a tissue-modified (humanized) mouse model of human ADME (absorption, distribution, metabolism, and excretion) toxicology. In brief, the mouse hepatocytes are destroyed *in vivo* and the liver is repopulated with human hepatocytes that function normally [87]. In this model, mice are genetically altered in such a way that leads to destruction of the native mouse hepatocytes. Two methods for destruction of the existing mouse hepatocytes have been reported: (i) expression of an albumin promoted urokinase-type plasminogen activator (uPA) or (ii) knockout of the fumarylacetoacetate hydrolase genes (Fah). In order for the human hepatocytes to repopulate the mouse liver, the mouse must be immunodeficient. This is accomplished

by using existing immunodeficient mice, for example, severe combined immunodeficiency (SCID) mice or genetic manipulation, such as knocking out the recombinant activation gene-2 (RAG-2). After injection of human hepatocytes into the mouse spleen, over time, the mouse liver will become repopulated with human hepatocytes replacing >70–90% of the native mouse hepatocytes.

The chimeric mouse model has been shown to be useful in evaluating the metabolism, disposition, pharmacokinetics, pharmacology, and toxicity of many xenobiotics [87,88]. Using chimeric mice, several authors have been able to demonstrate metabolic profiles that were specific to humans and different from wildtype mice, for example, dexamethasone (CYP3A4), diclofenac (CYP2C9), paclitaxel (CYP2C8), and debrisoquine (CYP2D6) [88]. The model has also been shown to be a predictor of circulating human metabolites especially metabolites derived from multiple metabolic reactions [89]. The chimeric mouse model was also able to predict the human disposition of the drug cefmetazole. In mice and rats, cefmetazole is eliminated in feces (bile), whereas in humans, urinary elimination of cefmetazole is found. When dosed to chimeric mice, cefmetazole was found to be eliminated in urine, similar to the human elimination pathway and different than the wildtype mouse [88]. Drug–drug interactions have also been evaluated in the humanized mouse liver model. For example, the human-specific CYP3A4 inducers rifampicin and rifabutin were shown to induce human CYP3A4 in the chimeric mice but not in wildtype mice. Also, inhibition of human CYP2D6 was demonstrated by using quinidine as an inhibitor and debrisoquine as the probe substrate. The AUC and $C_{\max}$ of 4-hydroxy debrisoquine decreased significantly in the $uPA^{-/-}$ /SCID humanized mice when codosed with debrisoquine and quinidine but did not change in the control $uPA^{-/-}$ /SCID mice [88].

2.3.4 Human

A great deal of metabolism-related information can be obtained through preclinical animal studies and *in vitro* human studies, such as metabolite identification and disposition of metabolites. However, none of these systems can act as a substitute for metabolism studies in healthy volunteers or patients. As quickly as the first human pharmacokinetic study in phase 1, information can be obtained on the identity of metabolites in human plasma and their concentrations relative to the parent drug either from single- or multiple-dose studies. Although these early phase 1 studies provide information on plasma metabolites and exposure, they often do not represent the full metabolic profile or the routes of parent drug and metabolite clearances. The human mass balance/AME (absorption, metabolism, elimination) study provides definitive information on metabolic and clearance pathways of metabolites and parent drug. This experiment, required by regulatory agencies, has several key outcomes: (i) an accounting of the mass balance of a drug and drug-related material through excretion into feces and urine; (ii) identification of rates and routes of elimination and clearance pathways (urine, bile, metabolism); (iii) quantitative identification of metabolites and metabolic pathways; and (iv) qualitatively and quantitatively supporting the use of preclinical toxicology species regarding exposure of metabolites between the preclinical species and humans (i.e., no unique human metabolites not found in preclinical toxicology species or human metabolites with much greater exposures than those found in preclinical species) [90].

In order to achieve these goals, a radioactive dose of the drug is given, generally carbon-14 (^{14}C , C-14) or hydrogen-3 (tritium, ^3H , H-3) and urine and feces are collected for 7–10 days. If significant amounts of parent drug or metabolites are expected to be eliminated in bile (based on animal data) then bile can also be collected and quantitated for parent drug and metabolites, as well as metabolite identification [91]. The study is conducted in healthy volunteers or patients ($\sim N = 4\text{--}6$) as a single oral therapeutic dose or as an intravenous dose if the intended route of clinical use will be intravenous [92,93]. The amount of radioactivity is “as low as feasible” without compromising the ability to identify metabolites and measure elimination routes. The typical amounts of radioactivity for C-14 and H-3 studies are $\sim 50\text{--}100\ \mu\text{Ci}$ and $100\text{--}300\ \mu\text{Ci}$, respectively [94]. Also important is the location of the radiolabeled element in the parent drug molecule. The site of radiolabel should be chemically and metabolically stable so that the radiolabel remains with the parent drug and parent drug/major metabolites and is not lost into the endogenous pool of biochemicals (e.g., release as carbon dioxide). In some situations, typically with compounds with a central amide or ester functionality, the drug molecule can be metabolically “split” into two components. In this case, the radiolabel will be retained in only a portion of the drug and the nonradiolabeled fragment will be difficult to follow and quantitate. When this occurs, two radiolabels are placed in the drug molecule so that both portions of the drug can be traced and a full accounting can be made of metabolic pathways and routes of elimination.

In humans, a successful mass balance study will account for 80–85% of the radioactive dose in urine and feces, which is generally achievable for a compound with a reasonable half-life ($< 50\text{ h}$). Roffey *et al.* have shown that when the human half-life of the drug is longer than 75 h, the ability to recover $> 80\%$ of the radioactive dose decreases dramatically. They found that 80% of drugs with a short half-life achieved 85% or greater recovery, whereas only 28% of drugs with a half-life of $> 75\text{ h}$ achieved 85% recovery [63]. In this situation, the collection period can be extended to collect more of the radioactive dose, but in some situations, the amount of radioactivity being eliminated at later times becomes too low to accurately measure, and it is no longer practical to continue collecting urine or feces. Fortunately, complete recovery of radioactivity from this study is not a requirement as long as the other objectives of the study are met, such as an understanding of routes of elimination and metabolic pathways, as well as exposure to metabolites similar to preclinical toxicology species.

The human radiolabeled mass balance/AME study provides a great deal of information about human *in vivo* metabolic pathways and the identification of metabolites and their exposure. This study provides a definitive and quantitative profile of metabolites found in human plasma. These can be inactive metabolites, pharmacologically active metabolites, or toxic metabolites. The FDA in 2008 published a guidance entitled “Safety Testing of Drug Metabolites” that describes how and when to identify and characterize drug metabolites whose nonclinical toxicity needs to be evaluated [95]. Since its publication in 2008, many other publications by the pharmaceutical industry have described how to practically address the situation of human metabolites that may need to be evaluated for toxicity [96]. Throughout the literature, these are known as *MIST* publications (Metabolites in Safety Testing). Although human *in vitro* systems do a reasonably good job of identifying major metabolic pathways, they cannot recapitulate the phenomenon of absorption, drug or metabolite disposition, elimination

(plasma, urine, bile, feces), or the combined effects of hepatic and extrahepatic (e.g., gut or kidney) metabolism.

2.4 METABOLISM STUDIES IN DRUG DISCOVERY AND DEVELOPMENT

2.4.1 Predicting Human Hepatic Clearance

In vitro metabolism studies using human liver microsomes or human hepatocytes to predict human metabolic clearance from the liver is routinely performed as early as drug discovery screening and throughout drug development. The ability to predict the metabolic clearance is important because the clearance is related to the exposure and half-life of the compound, two components that are essential in predicting the dosing regimen [20,97]. One of the major objectives of the pharmaceutical industry is to develop low dose drugs that are taken once a day thereby improving patient compliance and efficacy. In order to achieve this goal, drugs are often tested in human *in vitro* systems that assess metabolic stability. Compounds that are very rapidly metabolized are indicative of drugs that will have a high metabolic clearance and are therefore undesirable because they will require twice daily or three times a day dosing to achieve efficacy. Compounds that demonstrate no turnover or metabolism *in vitro* may indicate that the drug may have a long half-life in patients. Compounds with extremely long half-lives may be a benefit for some indications; however, they are also a concern should undesirable side effects or toxicity be uncovered for which the effects are prolonged because of the longer exposure time. Therefore, understanding the metabolic stability of both unstable and stable drug candidates is important to our understanding of dosing regimen, efficacy, and safety.

Liver microsomes and hepatocytes are two *in vitro* systems commonly employed to assess metabolic stability by measuring the disappearance of substrate over time [29,98,99]. The simplest method of assessing metabolic clearance is by incubating the compound of interest at a low substrate concentration (typically $<1 \mu\text{M}$) and measuring the disappearance of substrate. This “half-life” method uses the assumption that the substrate concentration is much lower than the K_m of the metabolic reaction(s), hence the low substrate concentration. This half-life method is often utilized in drug discovery during lead optimization because it has the potential to be high throughput when paired with human liver microsomes and provides a quick estimation of human metabolic clearance. The *in vitro* intrinsic clearance is determined from the following equation:

$$CL'_{\text{int}} = \frac{0.693}{\text{In vitro half-life} \times \text{microsomal protein concentration}}$$

For more sophisticated assessments of hepatic clearance, measurements of Michaelis–Menten kinetic parameters (K_m and V_{max}) are determined. From the rate of metabolism, the microsomal or hepatocyte intrinsic clearance (measure of enzyme activity) is determined. The *in vitro* intrinsic clearance (CL'_{int}) is then scaled to whole liver intrinsic clearance (CL_{int}) and incorporated into the following equation (well-stirred model of hepatic extraction) to estimate hepatic clearance (CL_H).

$$CL_H = \frac{Q \times f_u \times CL'_{\text{int}}}{Q + f_u \times CL'_{\text{int}}}$$

where Q = liver blood flow, f_u = fraction unbound in plasma, and intrinsic clearance is defined as $CL'_{int} = V_{max}/K_m$. See the chapter titled Enzyme Kinetics of Drug Metabolizing Reactions and Drug–Drug Interactions of this volume for additional information. This method is much more labor intensive and therefore not often used in drug discovery, however it does eliminate the assumption inherent in the half-life method and the need to use a low substrate concentration.

For drugs that undergo oxidative metabolism (e.g., CYP450 mediated) or glucuronidation, liver microsomes are a simple and effective *in vitro* system to predict hepatic clearance [98,100]. For compounds that undergo extensive phase II metabolism or metabolism via cytosolic enzymes, hepatocyte incubations are the more appropriate *in vitro* system. The same equations as illustrated above are also employed, however, the scaling factors will be different. In order to build confidence in the predicted human hepatic clearance determination from either microsomes or hepatocytes, *in vitro*–*in vivo* correlations of predicted and actual clearance values with several animal species should be performed. Assuming that the metabolism and clearance pathways are similar between the animal species and humans, this *in vitro*–*in vivo* correlation can support or refute the predictability of human *in vitro* hepatic clearance determinations.

2.4.2 Reaction Phenotyping

It is now widely accepted that the fraction of the dose metabolized (f_m) by a given drug-metabolizing enzyme is one of the major factors governing the magnitude of a drug interaction and the impact of a polymorphism on drug clearance. Therefore, pharmaceutical companies routinely determine the enzymes involved in the metabolism of potential new drugs *in vitro* and relate this information to human data on ADME [13,101,102]. This so-called reaction phenotyping or isozyme mapping, usually involves the use of multiple reagents, such as recombinant enzymes, liver microsomes, human hepatocytes, and clinical studies with polymorphic populations [103]. Through an understanding of the enzymes involved in the disposition of a new drug, investigators can predict potential drug interactions, such as those due to metabolism by polymorphic drug-metabolizing enzymes [104,105] (e.g., CYP2D6 or CYP2C9/19) or coadministration with potent inhibitors or inducers of CYP450 enzymes (e.g., a CYP3A4 substrate with ketoconazole or rifampin, respectively).

There are three *in vitro* techniques that can address reaction phenotyping and many researchers will utilize at least two of them if not all three [106]. The first technique utilizes recombinantly expressed single enzymes. In this situation, the drug of interest can be incubated with individual enzymes and turnover of parent or formation of metabolite(s) can be measured. Those enzymes that demonstrate turnover are considered to be involved in the metabolism of the compound. By scaling the amount of turnover with the amount of each particular enzyme in the human liver, the quantitative relative order (or ranking) of importance of each enzyme to the total metabolism of the compound can be calculated [6,13,101]. A second common approach utilizes human liver microsomes and selective chemical inhibitors or inhibitory antibodies for individual CYP450 enzymes. These chemical inhibitors or inhibitory antibodies selectively knockout or eliminate the activity of a single CYP450 enzyme and when compared to uninhibited incubations, the relative contribution of each CYP450 can be determined. For example, furafylline is a selective inhibitor of only CYP1A2 at a concentration of 20 μ and is routinely used to assess the contribution of CYP1A2 to the microsomal

TABLE 2.6 Chemical Inhibitors and Recommended Concentrations for CYP Reaction Phenotyping in Human Liver Microsomes

CYP Form(s)	Inhibitor	Inhibitor Concentrations
CYP1A2	Furafylline α -naphthoflavone	10–30 μ M ^a 1 μ M
CYP2A6	Methoxsalen	1 μ M
CYP2B6	ThioTEPA	50 μ M
CYP2C8	Montelukast	0.1 μ M
CYP2C9	Sulfaphenazole	10 μ M
CYP2C19	Benzylrivanol	1 μ M
CYP2D6 CYP2D6 & CYP3A4/5	Quinidine	<2 μ M and 10 μ M
CYP2E1	Diethyldithiocarbamate	50 μ M
CYP3A4/5 & others	Ketoconazole	1 μ M and 10 μ M
CYP3A4/5	Troleandomycin	50 μ M ^a

^aTime-dependent inhibitors (inhibition potency increases with preincubation in the presence of NADPH).

metabolism during reaction phenotyping studies [13,101]. Table 2.6 lists the common inhibitors used for CYP450 reaction phenotyping studies in human liver microsomes, many of which can also be used for inhibition studies in human hepatocytes. The third *in vitro* technique is termed *correlation analysis* whereby the rate of turnover of the substrate is compared to the rate of turnover of an isoform-selective probe substrate. A good correlation indicates that the enzyme is involved in the metabolism. For example, correlating the rate of metabolism of a drug candidate with the CYP3A4-mediated metabolism of midazolam (formation of 1-hydroxymidazolam is specific to CYP3A4) with preparations of human liver microsomes from 8 to 10 different donors. If the rates of metabolism demonstrate a good correlation, then it is presumed that CYP3A4 is involved in the metabolism of the compound.

It is important that the data are consistent between the three techniques to develop an integrated *in vitro* reaction phenotype for the substrate. In addition, these data are integrated with the overall elimination (metabolism, renal, biliary) of the parent drug so that the impact of a drug interaction can be ascertained. For example, consider two compounds both metabolized only by CYP2D6; however, compound A also undergoes significant renal elimination as parent drug but compound B does not undergo significant renal or biliary elimination. In this situation, compound A will not show a significant drug interaction (increase in parent drug exposure) in poor CYP2D6 metabolizers because renal elimination will provide a secondary elimination pathway. Compound B, however, would be expected to show significant increases in plasma exposure in CYP2D6 poor metabolizers because the drug has no elimination pathway besides CYP2D6-mediated metabolism.

For the human cytochrome P450s, reagents for reaction phenotyping are readily available, such as recombinant enzymes, specific chemical inhibitors/antibodies, and probe substrates for correlation analysis. Therefore, CYP450 reaction phenotyping is routinely performed and required for regulatory submissions. Recombinant enzymes are also available for most of the remaining drug-metabolizing enzymes (UGTs (UDP-glucuronosyltransferase), STs, FMOs), however, specific inhibitors, scaling factors, or probe substrates are not as readily available for many of these enzymes, which

severely limits the amount of information that can be extrapolated to human metabolism or potential drug interactions. Phase II glucuronidation is the second most common metabolic reaction after the CYP450 oxidations and reaction phenotyping is gaining momentum with these enzymes as well [107]. In recent years, new selective substrates and inhibitors have been identified for many of the UGT isoforms [100,108].

2.4.3 Drug–Drug Interactions

2.4.3.1 Enzyme Inhibition. Inhibition of drug-metabolizing enzymes will have a profound effect on any other drugs that are predominately eliminated by the same enzyme. In today's environment of poly pharmacy, many patients take more than one medication at a time and the risk of a drug–drug interaction also increases with the number of comedications. While CYP450 enzymes are the most significant drug-metabolizing enzyme family, inhibition of these enzymes has a major effect on drug concentration or exposure of coadministered drugs. Inhibitory drug interactions often cause exaggerated pharmacology or off-target toxicities because of increased plasma exposures and can result in serious side effects or death in extreme cases. Therefore, pharmaceutical companies and regulatory agencies are keen to reduce potential liabilities associated with inhibition of drug-metabolizing enzymes and eliminate such drugs being developed or marketed.

Two types of inhibition are routinely evaluated in drug discovery and development: reversible inhibition and irreversible inhibition (see Chapter 2 for kinetic details on each type of inhibition). Reversible inhibition is the easiest to determine and often included in high throughput screening in early drug discovery. Reversible inhibition can take the form of multiple mechanisms; however, the most common are competitive inhibition and noncompetitive inhibition (or a combination of the two referred to as *mixed inhibition*). Commonly, drugs that are substrates for P450 enzymes will also be inhibitors of the same enzyme (competitive inhibition), however, drugs can also inhibit CYP450 enzymes but not be substrates (noncompetitive inhibition). A common example is quinidine, which is a potent inhibitor of CYP2D6 but is not a substrate of CYP2D6 (quinidine is a substrate for CYP3A4).

Reversible CYP inhibition is routinely evaluated in early drug discovery by means of rCYP enzymes and fluorescent probes, which are both amenable to high throughput screening. Assays such as this are useful in assessing CYP inhibition potential (IC_{50} determination) or rank ordering of compounds or chemotypes and for the purposes of conducting SAR to eliminate a CYP inhibition liability. In order to determine a more accurate drug–drug interaction potential, most labs will perform inhibition studies with human liver microsomes (IC_{50} or K_i determinations) [106,109]. There is a considerable database of *in vitro* inhibition data related to human liver microsomes and clinical outcomes of drug–drug interactions. These correlations have resulted in a general categorization of potential drug interactions by means of the ratio of inhibitor concentration (efficacious plasma concentration, $[I]$) to the K_i .

$[I]/K_i > 1$ implies that a drug interaction is likely,

$1.0 > [I]/K_i > 0.1$ implies that a drug interaction is possible, and

$[I]/K_i < 0.1$ implies that a drug interaction is unlikely.

Going beyond the CYP enzymes, newer approaches evaluating other enzyme systems, such as glucuronosyltransferases or drug transporters and the use of human hepatocytes to predict drug–drug interactions are showing considerable promise to predict interactions with multiple enzyme systems and integrated pathways more accurately [27,109–111].

The second type of drug interaction known as *mechanism based-* or *metabolism-based inhibition* (MBI) is a result of inactivation of a drug-metabolizing enzyme by a metabolite or metabolic intermediate that forms an adduct with the enzyme (irreversible inhibition) or forms a metabolite-intermediate complex (MI complex) with the enzyme, also known as *quasi-irreversible inhibition* [18]. A classic example of irreversible inhibition was published by Trager *et al.* [112] with CYP1A2 and furafylline while a more recent example of MI-complex formation was published by Takakusa *et al.* [113] using lapatinib and CYP3A4 (both manuscripts provide detailed experimental protocols to assess these types of inhibition). Certain functional groups on drug molecules or natural products have a propensity to undergo reactive metabolite formation and cause irreversible inhibition. These functional groups include, but are not limited to, acetylenes, alkenes, organosulfo-compounds, arylamines, tertiary amines, cyclopropyl amines, hydrazines, furans, thiophenes, dihaloalkanes, and methylene dioxyphenyl containing compounds [114,115]. Whenever such structures are present in a molecule, rigorous testing should be conducted to evaluate the potential for reactive metabolite formation that can lead to irreversible inhibition or covalent binding to other macromolecules such as proteins and nucleic acids.

Drugs that cause irreversible inhibition distinguish themselves from ordinary reversible inhibition by several characteristics: (i) they may display a delayed onset of inhibition, (ii) their inhibition properties are typically greater than what would be expected from ordinary reversible inhibition parameters (IC_{50} or K_i), and (iii) the inhibition effects can persist after the inhibitor has been eliminated because of the fact that enzyme has been destroyed during the inactivation process and new enzyme must be synthesized to regain nominal enzyme levels. The mechanistic differences between reversible and irreversible inhibition require additional experimental methods to appropriately characterize the mechanism and potential drug–drug interaction from irreversible inhibition. For example, a simple test for reversible and irreversible inhibition is the IC_{50} shift method. Here, liver microsomes are preincubated (30 min) with the compound of interest at several concentrations with and without NADPH. Each sample is then diluted ($\sim 10\times$) into an incubation containing a probe substrate and NADPH to measure enzyme activity. A left-ward shift in the IC_{50} plot indicates an irreversible inhibitor. Irreversible inhibition is often referred to as *time-dependent inhibition* because the degree of inhibition increases with time, whereas with reversible inhibitors, the potency of inhibition does not change with time. The reference to time-dependent inhibition is for the most part correct, however, time-dependent inhibition can also be caused by formation of a metabolite that is itself a reversible inhibitor (and would show a similar left-ward shift). In this situation, the inhibition is referred to *reversible inhibition* but does characterize itself as time dependent because of the increasing concentration of the inhibitory metabolite with time. A more characteristic experiment, known as the *preincubation-dilution* method is commonly employed to determine the kinetic parameters of the inactivation process (K_I and K_{inact}) [106]. The K_{inact} is the maximum inactivation rate constant and the K_I is the inhibitor concentration that causes half maximal inactivation (or the dissociation

constant of the initial enzyme-inhibitor complex). Using these kinetic parameters of the inactivation process, a reasonable prediction of the magnitude of the drug interaction can be determined. A review of industry practices and methods to evaluate and interpret irreversible inhibition was recently published [116].

2.4.3.2 Enzyme Induction. The induction of drug-metabolizing enzymes or drug transporters can have significant consequences on the exposure and toxicity of drugs, that is, the efficacy of a drug is reduced if its clearance is increased by enzyme induction. For example, rifampin can decrease the AUC of coadministered drugs by as much as 70–90%, as in the case of (*R*)-verapamil coadministration with rifampin [117]. Another example of a clinically relevant induction drug–drug interaction is patients receiving cyclosporine (organ rejection), who are also treated with rifampin (tuberculosis) [118]. In contrast to inhibition where the drug immediately interacts directly with the enzyme and leads to toxic increases in drug exposure, induction is an indirect effect on the enzyme, generally taking days to result in a clinically relevant effect on drug elimination, which may persist for several days beyond cessation of the inducing agent. Induction of CYPs can also lead to toxicity by increasing reactive metabolite production or by increasing the CYP1A2-mediated activation of procarcinogens [119]. Recognizing the safety and health issues associated with exposure to inducing agents, the US Food and Drug Administration (FDA) and other regulatory agencies have placed more emphasis on determining whether a drug candidate has the potential to induce CYP or UGT enzymes, or drug transporters. In 2006, the FDA published a draft guidance on drug-interaction studies that presented details on the principles and conduct of *in vitro* induction studies. The Pharmaceutical Research and Manufacturer's Association (PhRMA) subsequently published a White Paper that addressed many of these issues and acknowledged the importance of appropriate study design [32].

The most common mechanism of CYP induction is transcriptional gene activation. For drug-metabolizing enzymes, transcriptional activation is mediated by transcription factors such as AhR (aromatic hydrocarbon receptor), CAR (constitutive androstane receptor), and PXR (pregnane X receptor or SXR-steroid X receptor) [120–125]. The general concept for nuclear receptor signaling, as exemplified by PXR, is that in the absence of a ligand (drug), the nuclear receptor is associated with corepressor complexes conferring a basal level of transcription. Drug binding to the ligand-binding domain (LBD) of the nuclear receptors induces conformational changes that lead to the release of corepressors and recruitment of coactivators. Subsequent dimerization with partner molecules (retinoid X receptor, RXR, for CAR/PXR and the AhR nuclear translocator, ARNT, for AhR) lead to chromatin remodeling and subsequent transcriptional activation. Regulation of target gene transcription is achieved through binding of the nuclear receptor DNA-binding domain (DBD) to respective DNA response elements present in the promoter region of target genes (drug-metabolizing enzymes) [125,126]. It should be noted that the LBDs of many nuclear receptors are different between various animal species and human [125]. Therefore, *in vitro* or *in vivo* animal models (e.g., rat and dog) of enzyme induction can be misleading and are generally not employed to assess the potential induction effect in humans.

The mechanisms of CAR- and AhR-mediated gene transcription differs somewhat from that of PXR, which is exclusively an agonist activated process. Both CAR and AhR can be activated by direct ligand binding as described above; however, they can also be activated by ligand binding independent mechanisms. Translocation of CAR

to the nucleus can be initiated by direct agonist binding to the receptor or through a partially elucidated ligand-independent mechanism involving kinases that dephosphorylate CAR. Phenobarbital is an example of a drug that does not bind to CAR yet causes nuclear translocation and transcriptional activation of the target gene, CYP2B6 [123]. Similarly, the inactive AhR resides in the cytoplasm and can be activated on ligand binding or via protein tyrosine kinases [127].

PXR-derived nuclear hormone receptor models (ligand binding and cell-based PXR transactivation assays) are the most common high throughput assays to evaluate enzyme induction due to the simplicity of ligand-based activation and the importance of PXR target genes, such as CYP3A4, CYP2B6, and CYP2Cs, in drug interactions. Although cell-based transcription activation assays exist for CAR (CYP2B6) and AhR (CYP1A); these are used less frequently and most often to address mechanistic questions.

Cultured primary human hepatocytes are the most widely accepted model for assessing the potential of drug candidates to induce human CYP expression [7]. The hepatocyte model is able to better predict the outcome of enzyme induction and drug interactions because of the ability to simultaneously capture multiple nuclear hormone receptor-mediated pathways rather than a single pathway as with the transcriptional activation models. Primary human hepatocyte culture systems have been shown to effectively model human *in vivo* induction responses and are recognized by regulatory agencies as an effective tool for assessing induction potential [128,129]. The enzyme induction data from *in vitro* methods are known to correlate well with clinical observations, provided the *in vitro* experiments are performed at pharmacologically relevant concentrations of drug [130]. In addition to CYP enzymes, numerous studies have been reported using primary hepatocyte culture systems to assess induction of a variety of gene targets from phase II enzymes and drug transporters [131–134]. The pharmaceutical industry and regulatory agencies recommend the analysis of RNA expression and catalytic activity of the major drug-metabolizing enzymes CYP1A2, CYP2B6, and CYP3A4 in freshly isolated or attachable cryopreserved hepatocyte cultures. Results should be obtained from at least three individual donors, treated with the test compound, vehicle, and positive controls for two to three days. A minimum of three test compound concentrations, based on the expected human plasma drug levels are suggested, one of which should be an order of magnitude greater than this concentration. In the absence of knowledge of human plasma levels, concentrations ranging over at least two orders of magnitude should be studied.

Immortalized hepatocytes have been shown to possess many of the characteristics of primary hepatocytes. The advantages of using immortalized cell lines primary hepatocytes for enzyme induction studies include (i) easy access and availability; (ii) the ability to propagate (i.e., continual supply); and (iii) more consistent induction response compared to the variability seen with multiple donors of human hepatocytes. Immortalized cell lines cited throughout the literature include HepG2, HepaRG, Fa2N-4, and BC2 [135,136]. HepG2 and HepaRG cells have been shown to respond, to varying degrees, to CYP1A1/2 and 3A4 inducers [137–139], Fa2N-4 cells respond to rifampicin and β -naphthoflavone in a similar manner as observed for primary human hepatocytes [135,136], and BC2 cells have been reported to respond to CYP1A inducers [140]. While these cell lines can be used for preliminary studies, they do not maintain all of the phenotypic characteristics of human hepatocytes, such as enzyme or receptor function or expression, and their use may result in erroneous conclusions.

Interpretation of *in vitro* induction results can be as simple as compared to known CYP3A4 inducers (e.g., rifampin) or rank ordering of potency (EC_{50}) both of which provide useful information. Accurate predictions of drug interactions incorporate therapeutic drug concentrations, such as therapeutic drug concentrations (C_{max} or C_{ss}) along with induction data. Combining values, such as EC_{50} , E_{max} , and C_{max} (E_{max} mathematical model) have been used to assess induction effects for multiple induction models (transactivation, immortalized hepatocytes, and primary hepatocytes) [136,141,142]. More advanced mathematical models include such parameters as fraction unbound in hepatocyte culture, fraction metabolized, and a scaling factor (d), which allows better correlations between *in vitro* and *in vivo* outcomes of induction [32]. Another method of data interpretation is more empirical and involves correlations between the induction response found *in vitro* and the response *in vivo*. The most utilized form of correlation analysis utilizes the relative induction score (RIS), which has shown utility with both immortalized hepatocytes and primary hepatocytes [32,136].

2.5 FUTURE DIRECTIONS

The science of drug metabolism is continuing to move forward at an extremely fast pace, which is both a blessing and a curse. Without a doubt, the discipline is constantly growing with new information, methodologies, and instrumentation appearing as a continual stream in manuscript and presentation formats. At times, it can be challenging to keep abreast of the plethora of information reported in manuscripts across the field. Although this is a challenging time, it is also an exciting time to contribute to the wealth of information being generated today and to contribute to the future of drug metabolism.

One of the greatest challenges in drug metabolism is the predictive nature of our *in vitro* and animal models to human pharmacokinetics, metabolism, and toxicity. Most models appear to be qualitative or semiquantitative in their ability to accurately predict human outcomes. Moving down this “predictivity scale” to quantitative predictions with *in vitro* and animal models is the future direction of drug metabolism. This goal can be achieved through improvements of our existing models (e.g., hepatocytes), development of new models, and a better understanding of data analysis and data interpretation of both current and new models. Several of the new models that show great promise include the development of genetically modified animals [78,83] and stem cell derived hepatocytes [143,144]. Genetically modified animals provide an opportunity to evaluate human enzymes, receptors, transporters, or combinations of these, sometimes integrated events, in an *in vivo* setting. This should provide a significant improvement on evaluating events precipitated from these biological mediators through individual *in vitro* systems. Stem cell derived hepatocytes would significantly improve our ability to employ human hepatocytes across a number of existing *in vitro* methods, such as metabolite generation, predictions of hepatic clearance, and toxicity. Stem cell derived hepatocytes would provide a renewable and consistent supply of cells that are more stable in culture (expression and function of enzymes) and survive longer in culture so as to be useful in better predicting hepatic clearance or metabolite formation of slowly metabolized compounds, as well as toxic events that take longer to manifest in culture. Once these two advances become more established, the field will once again take a

large step forward, much like it did with the advent of molecular biology techniques in the 1980s and 1990s.

3.1 INTRODUCTION

In vitro studies play an important role in characterizing biotransformation reactions. Kinetic parameters are determined during the early phases of drug discovery and development and provide invaluable information needed to predict *in vivo* metabolism and assess potential interactions with enzyme effectors. These *in vitro* studies are routinely used for estimating kinetic parameters, such as K_m and V_{max} . Under linear conditions, the ratio of V_{max} and K_m represents the metabolic intrinsic clearance (CL_{int}), which is assumed to also be representative of the *in vivo* CL_{int} of a compound. Thus, it follows that this calculated CL_{int} value can then be used to extrapolate *in vitro* kinetic data to *in vivo* metabolic clearance and subsequently, the initial dose of a drug to be used in humans. To a great extent, this approach has provided reliable and successful *in vivo* clearance predictions. However, this success is predicated on accurate estimations of *in vitro* enzyme kinetic parameters. This chapter describes the proper conditions for carrying out *in vitro* enzyme kinetic experiments and the potential caveats that may lead to erroneous results. Also described are the various types of kinetic profiles that may be observed and equations that can be used to estimate kinetic parameters based

on the type of kinetics. Finally, methods for determining a compound's potential for drug-drug interactions with other substrates of the same enzyme are described, along with kinetic models to assess inhibition potential.

3.2 CONFOUNDING FACTORS OF *IN VITRO* EXPERIMENTS

3.2.1 General *In Vitro* Incubation Conditions

It is vital to obtain reliable and accurate *in vitro* data that reflect the *in vivo* situation. Therefore, fundamentally sound enzyme kinetics practices must be employed and reaction conditions must be well defined. There are multiple factors to consider when determining which *in vitro* incubation conditions are appropriate and best mimic the *in vivo* system. The most important experimental components in drug metabolism reactions are substrate concentration, incubation time, and protein concentration. An appropriate length of time for an incubation reaction should allow for adequate product formation to ensure precise quantitation. It is equally important that the substrate turnover be linear with respect to incubation time and enzyme concentration. Initial experiments are needed, where product formation is measured at multiple time points in incubations containing different concentrations of protein. From these studies, an incubation time and protein amount can be chosen for all subsequent experiments where the same enzyme source is used. In practice, for many drug-metabolizing enzymes, a protein concentration of 0.1–0.25 mg/mL and an incubation time of 5–10 min will produce a linear reaction with readily detectable conversion of substrate (see below for discussion of the role of protein concentration and nonspecific binding to microsomal proteins). If nonlinearity is observed with respect to velocity, autoinactivation of the enzyme or too much substrate depletion may be occurring. The substrate concentration should be greater than 10-fold excess compared to the enzyme concentration, and <10% of the substrate should be consumed [1,2]. Experiments should include multiple time points (8–10 points), generally ranging from one-fifth to fivefold the K_m value. To this end, iterations of the experiment may be needed to establish the proper experimental conditions of enzyme concentration, time, and substrate concentration range to adequately describe the kinetic profile of the metabolism reaction.

Optimization of other experimental variables is equally as important when designing and conducting *in vitro* experiments to be used to determine kinetic parameters. Other important parameters that may affect metabolic rate and should be given careful consideration include selection of buffer system, buffer ionic strength, incubation pH, and incubation temperature. The *in vitro* experimental variables of temperature, pH, and buffer ionic strength are usually set to reflect human liver physiological conditions. Generally, one tries to employ buffer conditions that mimic the *in vivo* situation. For example, commonly used buffers include 50–100 mM potassium phosphate buffer or tris-hydroxyaminomethane (THAM) at pH 7.4 maintained at 37°C [3]. In addition, cosubstrates such as nicotinamide adenine dinucleotide phosphate (NADPH) or uridine diphosphate glucuronic acid (UDPGA) should not be rate limiting and are typically included at saturating concentrations during the incubation. Typical concentrations of NADPH used range from 0.5 to 2 mM and UDPGA, 3–5 mM. Alternatively, an NADPH-regenerating system may be utilized if one is concerned about maintaining NADPH concentrations, especially over longer incubation periods. However, typically

this is not an issue in incubations up to 1 h since the concentrations of NADPH suggested are significantly above the K_m for NADPH and, thus, depletion due to conversion to NADP is not usually an issue. Because the composition of the incubation matrix could potentially affect various enzymes differently, a systematic evaluation should be conducted to determine optimal experimental conditions [4,5].

Multiple studies have evaluated the effects of different buffering systems on kinetic parameter estimates; however, not all the reported findings are in agreement [6,7]. Irrespective of which buffer is chosen for the incubation mixture, it is important to maintain pH within the physiological range. Yao and Levy [3] have reported differences in *in vitro* K_i values due to small changes in pH from 7.2 to 7.6. These findings suggest that this should be an area of further research in order to optimally define *in vitro* incubation conditions that most accurately reflect the microenvironment of hepatic smooth endoplasmic reticulum.

3.2.2 Effect of Organic Solvents on Enzyme Activity

In an attempt to mimic the microenvironment of the human liver, *in vitro* studies are carried out in aqueous physiological buffers. However, owing to the lipophilic nature of many drug substrates and inhibitors, potential solubility problems arise. To overcome these issues, organic solvents such as methanol, ethanol, acetonitrile, and dimethyl sulfoxide (DMSO) are commonly used to facilitate compound solubilization. The presence of organic solvents in the incubation reaction may, however, alter enzyme–substrate interactions by modifying the native enzyme environment or altering enzyme activity. It is important that one considers these potential effects because any changes resulting from the presence of organic solvent could potentially compromise the reliability and interpretation of the *in vitro* data.

The effect of organic solvents in the incubation reaction on individual cytochrome P450 (CYP) enzyme activity of microsomal, hepatocyte, and recombinant enzyme systems has extensively been investigated [8–11]. The observed effect on individual CYP activity is solvent specific. For example, Vuppugalla *et al.* [10] reported no effect on CYP2B6 or CYP2C8 activity when 0.5% (v/v) methanol was present, whereas the presence of ethanol, acetonitrile, and DMSO showed concentration-dependent inhibition from 0.2% to 5%. Although results typically are in agreement, some discrepancies have been reported. It has been reported that 1% acetonitrile has no effect on CYP1A2 activity in human hepatocytes [11] or on cDNA-expressed recombinant enzymes [8], but it results in increased CYP1A2 activity in human liver microsomes [12,13]. These results suggest that the degree of inhibition may be enzyme-source dependent.

Although numerous studies have reported inhibitory effects on CYP enzyme activity because of the presence of organic solvent, stimulatory effects have been observed [8,14,15]. The presence of acetone (2–4% v/v) or acetonitrile (2–4% v/v) in kinetic studies using human liver microsomes or reconstituted CYP2C9 resulted in increased tolbutamide hydroxylation. The reported stimulatory effect was observed over a wide range of substrate concentrations. Similar findings were described by Tang and others [9] who observed an increase in CYP2C9 activity toward diclofenac 4'-hydroxylation and tolbutamide methyl hydroxylation. However, acetonitrile inhibited celecoxib methyl hydroxylation, suggesting that the stimulatory effect of acetonitrile on CYP2C9 activity is substrate dependent.

A given organic solvent may exhibit differential inhibitory or stimulatory effects on specific CYPs. Although purely aqueous incubation conditions are preferred for *in vitro* CYP metabolism studies, in practice, it is likely that the use of organic solvent will be required to facilitate enhanced solubility of the compound of interest. Thus, the organic solvent concentration must be kept to an absolute minimum and, generally, <1% of the total reaction volume. In addition, it is important to identify suitable solvents that enable *in vitro* studies to be completed with minimal effect on CYP activity.

3.2.3 Nonspecific Microsomal Binding

Human liver microsomes are the most popular and widely used *in vitro* system for evaluating drug metabolism due in part to their reasonable availability, low cost, and ease of use. However, numerous examples exist in the literature of nonspecific binding of drug substrates (and inhibitors) to microsomal proteins. Margolis and Obach [16] reported that the use of high microsomal protein concentrations (especially 0.5 mg/mL and greater) caused alterations of inhibition constants for drugs that were highly lipophilic because of nonspecific binding effects. Therefore, it is desirable to use the lowest amount of protein that yields quantifiable amounts of metabolite in order to minimize these effects [1,2]. Lipophilicity is a characteristic shared by most drugs, and therefore, it is not surprising that many substrates have been shown to readily bind nonspecifically to the protein milieu of the microsomal membrane. The extent of nonspecific binding varies among drug classes and is dictated by the physiochemical characteristics of the drug [17–19]. Drugs that are weak bases, such as amiodarone and amitriptyline, bind extensively to the microsomal membrane, whereas others that are weak acids, such as naproxen and tolbutamide, exhibit relatively little or no microsomal binding [18–20]. When drugs bind nonspecifically to microsomal proteins, the effective free substrate concentrations will be less than the amount added, leading to inaccuracies in the determination of K_m and K_i parameters. The apparent K_m (or K_i value in the case of inhibition experiments) observed will be higher than the true K_m , although there should be no effect on V_{max} [20]. Thus, an overestimation of K_m occurs and *in vivo* drug clearance will be underestimated, unless the actual free substrate concentration in the reaction mixture is determined (i.e., nonspecific binding is measured). Several groups have proposed various correction factors to be applied for nonspecific binding during extrapolation to *in vivo* clearance [19–21]. For drugs that exhibit extensive nonspecific binding, correction for microsomal binding using free fraction in incubation matrices improves the prediction of *in vivo* clearance values calculated from *in vitro* estimates of intrinsic clearance. However, one cannot simply correct the apparent K_m value by multiplying the unbound drug fraction because this rule does not apply to every enzymatic reaction [9].

3.3 DETERMINATION OF ENZYME KINETICS

3.3.1 Michaelis–Menten Kinetics

In typical enzyme-catalyzed reactions, the substrate and product concentrations are much greater than the enzyme concentration such that each enzyme molecule catalyzes the conversion of multiple substrate molecules to product. The conversion of substrate

to product involves the formation of a transition state that occurs at the catalytic, or active, site of the enzyme.

Generally, kinetic characterizations of most enzymatic reactions are governed by hyperbolic kinetics that can be described by the Michaelis–Menten equation (Eq. 3.1).

$$v = \frac{V_{\max} [S]}{K_m + [S]} \quad (3.1)$$

The Michaelis–Menten equation is a quantitative description of the relationship that exists among the rate of an enzyme-catalyzed reaction (v), the concentration of substrate $[S]$, and the two parameters, $V_{\max}$ and K_m . In this case, $V_{\max}$ is the maximal velocity of the reaction and K_m is the Michaelis constant. General characterization of the enzymatic reaction can be determined in terms of rate and concentration by means of this equation. However, it is important to keep in mind three general considerations that are made when describing kinetic data modeled after the Michaelis–Menten equation: (i) the enzymatic reaction is operating under steady-state conditions, (ii) rapid equilibrium between the concentration of all the enzyme–substrate intermediates becomes constant soon after initiation of the reaction, and (iii) the catalytic active site of the enzyme contains only one binding site at which one substrate molecule can interact at a given time.

The fundamental concepts underlying these kinetic analyses continue to provide the cornerstone for understanding drug metabolism today, and are routinely used during drug development to determine kinetic constants ($V_{\max}$ and K_m) in the analysis of *in vitro* drug metabolism data. The Michaelis constant, K_m , is strictly defined as the concentration of substrate at which half-maximal velocity of the reaction is achieved. It is important to recognize that the determination of this rate constant results from the combination of several rate constants such that K_m is equal to (Scheme 3.1), where E, S, ES, and P are the concentrations of the enzyme, substrate, substrate-bound enzyme, and enzyme products (metabolites), respectively. The association rate constant of $E + S \rightarrow ES$ is depicted as k_1 , whereas k_{-1} is the dissociation rate constant for $ES \rightarrow E + S$ and k_2 is the dissociation rate constant of $ES \rightarrow E + P$. Often, K_m is incorrectly associated with the affinity of the substrate for the enzyme, but as can be seen from the above discussion, K_m is a composite of three rate constants. More exactly, k_{-1}/k_1 (referred to as K_s or K_d), which is the substrate dissociation constant, reflects substrate affinity.

The definition of $V_{\max}$ is derived from the product of k_{cat} and e_0 ($k_{\text{cat}} \times e_0$), where k_{cat} (or k_2 , as referred to in Scheme 3.1) is the capacity of the enzyme–substrate complex to form product and e_0 is the enzyme concentration. The k_{cat} parameter is a reflection of the number of molecules of substrate that one molecule of enzyme can convert to product per unit time. For this reason, k_{cat} is also referred to as the *catalytic constant* or the *turnover number*.

The velocity of the reaction can be characterized as a hyperbolic, saturating profile. The key features of the substrate concentration versus reaction velocity plot are depicted

Scheme 3.1

Figure 3.1 Hyperbolic saturation curve depicting typical Michaelis–Menten kinetics.

in Fig. 3.1. At high substrate concentrations, the rate of the reaction, represented by the point C, is almost equal to $V_{\max}$, and rate differences at reasonably similar substrate concentrations are negligible. It should be noted that $V_{\max}$ is only an estimate, as the maximal velocity of the enzymatic reaction is never reached at a finite substrate concentration. If, however, the Michaelis–Menten plot is extrapolated to infinitely high substrate concentrations, the extrapolated rate is equal to $V_{\max}$. At this point, the reaction becomes nearly independent of substrate concentration, and the rate is said to be zero order. At lower substrate concentrations, such as the areas of the curve before K_m (point B), the lower reaction velocities are indicative of only a portion of the enzyme molecules being occupied by substrate. Therefore, at low substrate concentrations (i.e., point A), the rate of the reaction is directly proportional to substrate concentration and the reaction is said to be first order.

Estimation of K_m and $V_{\max}$ is useful during the drug development process since these parameters can be used to estimate the *in vitro* intrinsic clearance (CL_{int}) for a drug, which in turn can be extrapolated to estimate the *in vivo* CL_{int} . The extrapolated parameter (CL_{int}) can then be used to predict *in vivo* hepatic clearance and subsequently total (systemic) clearance, and drug dosing. To do this, one makes the assumption that *in vivo*, the substrate concentration will be much lower than the K_m . Under these conditions, the $[S]$ term drops out of the denominator and Equation 3.1 becomes Equation 3.2.

$$v = \frac{V_{\max}[S]}{K_m} \quad (3.2)$$

In Equation 3.2, the velocity is proportional to $[S]$ and is equal to the product of CL_{int} and $[S]$ (Eq. 3.3).

$$v = CL_{\text{int}}[S] \quad (3.3)$$

Since *in vivo* CL_{int} is defined as the ability to clear drug in the absence of blood flow or protein-binding restrictions, the *in vivo* CL_{int} should be equal to the *in vitro*

CL_{int} . Because Equations 3.2 and 3.3 are analogous, the equations can be rearranged as (Eq. 3.4)

$$CL_{int} = \frac{V_{max}}{K_m} = \frac{v}{[S]} \quad (3.4)$$

This equation then allows derivation of CL_{int} following estimation of the *in vitro* enzyme parameters, K_m and V_{max} .

3.3.2 Non-Michaelis-Menten Kinetics

Unfortunately, not all enzyme reactions carried out by drug-metabolizing enzymes can be adequately described by Michaelis–Menten kinetics (i.e., they do not exhibit a hyperbolic kinetic profile). These types of kinetic profiles have been observed with several of the CYP drug-metabolizing enzymes, most commonly, CYP3A4, and also with most other drug-metabolizing CYPs. However, atypical kinetic profiles have also been observed with other important drug-metabolizing enzymes such as the UGTs (UDP-glucuronosyltransferases) [22–24].

Most commonly, atypical kinetic profiles observed with drug-metabolizing enzymes have been attributed to the binding of multiple molecules of a substrate (homotropic) or two chemically different substrate molecules (heterotropic) within the enzyme active site. The binding of one molecule can change the kinetics of a second substrate molecule binding within the active site and is frequently referred to as *cooperativity*. This cooperativity is characterized as being homotropic or heterotropic depending on the chemical species present in the enzyme active site. This cooperativity can be either positive or negative, depending on the effects elicited by the second substrate molecule. Although the term *allosterism* is generally used to describe cases where a second molecule binding distant to the substrate molecule causes an alteration in the functioning of the enzyme, it is also sometimes used to describe the kinetic changes due to a second substrate molecule binding since it is separate from the original substrate but may be still within the active site. However, it should also be realized that these types of kinetics may also be due to the presence of multiple species of the enzyme (e.g., conformers) that exhibit different kinetic characteristics with a substrate.

3.3.2.1 Sigmoidal Kinetics. Numerous examples of activation, or positive cooperativity, in drug-metabolizing enzymes are found throughout the literature [25]. Activation occurs when enzyme activity for a substrate is increased either by the presence of another compound or a single compound activating its own metabolism. Autoactivation is an example of homotropic cooperativity and is characterized by a sigmoidal kinetic profile. This profile is thought to occur because of the simultaneous binding of two molecules of the substrate within the enzyme active site, with the metabolism of one of the substrate molecules exhibiting a low K_m and low V_{max} and the other exhibiting a higher K_m and higher V_{max} (Fig. 3.2). A useful tool in establishing the presence of sigmoidicity in a kinetic plot is to identify deviations from linearity when the data are presented in an Eadie–Hofstee plot. A marked increase in the curvature, or hooked nature, of the line is indicative of a sigmoidal profile (Fig. 3.3). These data are indicative of positive cooperativity and suggest the presence of multiple interactions between the substrate and enzyme. Altered affinity and rate of product formation for other substrate binding sites may result from these interactions.

Figure 3.2 Sigmoidal saturation curve of velocity versus substrate concentration.

Figure 3.3 Eadie–Hofstee plots of typical and atypical kinetics. (a) Hyperbolic (Michaelis–Menten kinetics), (b) sigmoidal kinetics, (c) biphasic kinetics, and (d) substrate inhibition kinetics.

One of the most commonly used equations to describe sigmoidal kinetic profiles is the Hill equation [26] and is commonly used to mathematically describe sigmoidal kinetic profiles (Eq. 3.5).

$$v = \frac{V_{\max} [S]^n}{K' + [S]^n} \quad (3.5)$$

Although the K' parameter is analogous to K_m , it is not equivalent (unless $n = 1$) as it is composed of both K_m and the interaction factors [27]. The coefficient n , referred to as the *Hill coefficient*, reflects the degree of cooperativity observed. It should be

noted that n does not relate to the number of binding sites within the enzyme. Values of $n > 1$ are indicative of positive cooperativity, and the greater the n value, the greater the sigmoidicity of the kinetic profile.

Although applicable to most sigmoidal kinetic data, the Hill equation provides limited information about the actual kinetic processes and the associated rate constants. In an attempt to overcome these limitations and gain additional insight into the substrate–enzyme interaction, more complex kinetic models have been proposed [28,29]. These models are based on the assumption of two equivalent substrate binding sites within the enzyme active site. Korzekwa *et al.* [29] derived velocity equations to fit sigmoidal kinetic observations, thereby allowing one to estimate two K_m values (K_{m1} and K_{m2}) and two V_{max} values (V_{max1} and V_{max2}) (Eq. 3.6), ostensibly representing the kinetic processes at each of the binding sites.

$$v = \frac{\frac{V_{max1}}{K_{m1}} + \frac{V_{max2}}{K_{m1}K_{m2}}}{1 + \frac{[S]}{K_{m1}} + \frac{[S]^2}{K_{m1}K_{m2}}} \quad (3.6)$$

A more detailed model that provided additional insights into the micro rate constants of the various processes was proposed by Shou *et al.* [27], again modeling two binding sites within the enzyme active site. A kinetic scheme was proposed that discriminates all possible equilibrium and rate steps of each of the enzyme–substrate complexes possible within the two binding sites.

The following equation (Eq. 3.7) was derived based on Scheme 3.2 for estimation of the associated kinetic parameters:

$$\frac{v}{[E]_{total}} = \frac{\frac{k_\alpha}{K_{S1}} + \frac{k_\beta}{K_{S2}} + \frac{[S]}{K_{S1} \times K_{S3}} \times (k_\delta + k_\gamma)}{\frac{1}{[S]} + \frac{1}{K_{S1}} + \frac{1}{K_{S2}} + \frac{[S]}{K_{S2} \times K_{S4}}} \quad (3.7)$$

3.3.2.2 Biphasic Kinetics. Biphasic kinetic profiles are another example of homotropic cooperativity, but unlike sigmoidal kinetics, biphasic kinetics profiles do not reach saturation, but rather exhibit two distinct phases (Fig. 3.4). The first phase is observed at low substrate concentrations and is more characteristic of hyperbolic

Scheme 3.2

Figure 3.4 Biphasic saturation curve of velocity versus substrate concentration.

kinetics. At increasing substrate concentrations, the second phase becomes evident as the velocity of the reaction continues to increase linearly, with no evidence of saturation. However, one must be cognizant that “apparent” biphasic kinetic profiles may appear in multienzyme systems, where two enzymes are producing the same metabolite but with dramatically different kinetics, such that one enzyme is a high affinity–low capacity enzyme and the second enzyme is a low affinity–high capacity enzyme. In true biphasic kinetics, the same enzyme is operating with both a low- and high-affinity binding component [29]. If a biphasic kinetic profile is observed within a single enzyme system, it most likely results from multiple binding regions within the active site, or the substrate binds within the active site in multiple orientations. Regardless, the binding orientation responsible for the semihyperbolic portion of the profile will result in a low K_m , low V_{max} component, whereas the other binding orientation will produce a high K_m and high V_{max} . A kinetic equation has been developed, essentially a combination of the Michaelis–Menten equation and a linear equation, to describe biphasic kinetics (Eq. 3.8):

$$v = \frac{(V_{max1}[S]) + (CL_{int}) \times [S]^2}{(K_{m1} + [S])} \quad (3.8)$$

From this equation, the parameters derived from fitting the equation to the initial curved portion of the plot provide estimates of V_{max1} and K_{m1} and are reflective of low substrate concentrations. The CL_{int} parameter describes the linear portion of the profile that occurs at high concentrations and can be determined from the ratio of V_{max2}/K_{m2} (i.e., the slope of the linear portion of the kinetic profile).

3.3.2.3 Substrate Inhibition. Substrate inhibition occurs when the rate of product formation plateaus at a point and then decreases with increasing substrate concentrations (Fig. 3.5). To model substrate inhibition and derive kinetic parameter estimates, an equation has been derived based on the uncompetitive inhibition model (Eq. 3.9). From this equation, one can estimate the kinetic parameters K_m , V_{max} , and K_{si} (i.e., inhibition constant for the second substrate molecule).

Figure 3.5 Substrate inhibition saturation curve of velocity versus substrate concentration.

$$v = \frac{V_{\max}[S]}{K_m + [S] + \frac{[S]^2}{K_{si}}} \quad (3.9)$$

However, this kinetic model, apart from the K_m and $V_{\max}$ estimations, only provides insight into the inhibition constant of the substrate and not into more of the micro rate constants of formation and dissociation of the various possible species present. To better describe the various rate constants associated with all possible species and processes involved in substrate inhibition, a more complex kinetic model was proposed (Scheme 3.3) [30].

This model is based on the premise that one binding site is catalytic and the other inhibitory and that substrate molecules have access to both these sites. When the substrate (S) binds to the catalytic site of the enzyme (i.e., ES), the rate and $V_{\max}$ of product formation ($ES \rightarrow P$) are determined by $k_p[ES]$ and $k_p[E]_{\text{total}}$, respectively. In contrast, once excess S binds to the nonproductive, inhibitory site (SE) the rate of S-E-S is no longer the same as ES and is reduced by a factor β . This model incorporates sequential binding of substrate molecules such that the substrate inhibition site cannot

Scheme 3.3

be occupied until the active site is filled and the second site may be independent from the active site.

On the basis of this scheme, an equation was derived to describe substrate inhibition, based on the assumption that the rates of formation and of decomposition of the various enzyme-substrate complexes are equivalent (Eq. 3.10) [30].

$$v = \frac{V_{\max} \left[\frac{1}{K_S} + \frac{\beta \times [S]}{(\alpha \times K_i \times K_S)} \right]}{\frac{1}{S} + \frac{1}{K_S} + \frac{1}{K_i} + \frac{[S]}{(\alpha \times K_S \times K_i)}} \quad (3.10)$$

In this equation, K_S is approximately equal to K_m , and K_i is the dissociation constant of the substrate binding to the inhibitory site. Alpha (α) represents the factor by which the dissociation of substrate (K_S and K_i) at both sites is altered when a second molecule is bound, whereas β is the factor by which $V_{\max}$ changes on binding of a second substrate molecule. It is evident that the use of this equation allows for additional parameter estimations and provides useful information as to the degree to which binding of the second substrate molecule alters K_m and $V_{\max}$. However, it should be noted that because of the number of parameters to be estimated, properly fitting data to this equation requires acquisition of a substantial number of data points.

3.3.2.4 Heteroactivation Kinetics. During *in vitro* studies to evaluate potential drug-drug interactions, one typically expects to observe inhibition using microsomal or expressed enzyme systems. However, it is now well established that *in vitro* coincubation of two different compounds can also result in increased metabolism of one substrate rather than inhibition [25,29] (Fig. 3.6). Again, this phenomenon

Figure 3.6 Heteroactivation plot depicting the relationship between the metabolite, effector molecule, and substrate.

Scheme 3.4

has been attributed to the simultaneous binding of two different molecules, substrate and effector, within the active site. However, it should be realized that the “effector” may also be metabolized itself. This positive cooperativity typically results in both a decrease in K_m and an increase in V_{max} . This heteroactivation is depicted in Scheme 3.4.

This kinetic scheme has been described by a complex equation (Eq. 3.11) that allows for determination of the kinetic parameters above:

$$v = \frac{V_{max} \times [S]}{K_m \left(\frac{1 + \frac{[B]}{K_B}}{1 + \frac{\beta[B]}{\alpha K_B}} \right) + [S] \left(\frac{1 + \frac{[B]}{\alpha K_B}}{1 + \frac{\beta[B]}{\alpha K_B}} \right)} \quad (3.11)$$

where B is the concentration of activator, α is the factor by which the K_m for substrate changes, and β can be thought of as the factor by which V_{max} changes. This equation allows for fitting multiple curves representing different activator concentrations and has a manageable number of parameters including the usual K_m and V_{max} for substrate in the absence of activator.

3.4 GRAPHICAL PRESENTATION OF KINETIC DATA TO IDENTIFY ATYPICAL KINETIC PHENOMENA

The most appropriate method of generating enzyme kinetic parameter estimates is the use of computer-generated, nonlinear regression analysis of the untransformed data using a suitable model. However, in the analysis of enzyme kinetics data, much value can be gained by examining a graphical representation of the kinetic data. Graphical plotting of the data can provide additional insights into interpretation of whether the data are truly hyperbolic and follow Michaelis–Menten kinetics or whether atypical kinetic phenomena may be operational. Thus, graphical presentations of the data can aid in determining the correct kinetic model to apply in estimating kinetic parameters.

3.4.1 Eadie–Hofstee Plot

The Eadie–Hofstee plot is based on the transformation of the Michaelis–Menten equation to give the equation of a straight line. In this case, the v is plotted along the y-axis and $v/[S]$ along the x-axis (Fig. 3.3). The slope of the best-fit line is equal to $-K_m$, the y-intercept = V_{max} , and the x-intercept = V_{max}/K_m . As with other graphical

representations, the Eadie–Hofstee plot is not without caveats. The Eadie–Hofstee plot has the disadvantage that the velocity appears in both coordinates. Because the x -axis contains an element of the velocity, it no longer reflects a truly independent variable. As a result, any experimental errors will be reflected on both axes. Therefore, otherwise seemingly good data can appear worse. On the other hand, this plot best reveals the presence of atypical kinetic profiles based on the shape of the data-fit obtained. For example, a linear Eadie–Hofstee plot of the data would be representative of hyperbolic (Michaelis–Menten) kinetics, a “hooked” Eadie–Hofstee plot suggests sigmoidal autoactivation kinetics, a biphasic Eadie–Hofstee plot suggests biphasic kinetics, and an Eadie–Hofstee plot where the plot rises and then falls similar to the substrate versus velocity plot of substrate inhibition would, of course, suggest that substrate inhibition is occurring.

3.5 DRUG-DRUG INTERACTIONS DUE TO ENZYME INHIBITION

Drug–drug interactions continue to be an obstacle for the pharmaceutical industry, and thus, accurate predictions of potentially adverse clinical outcomes become increasingly important in drug discovery and development. The determination of *in vitro* enzyme inhibition kinetics is an important predictor of potential drug–drug interactions. Enzyme inhibition is the decrease in the rate of substrate turnover in the presence of an inhibitory effector molecule. Enzyme inhibitors fall into two broad classes—reversible and irreversible [30]. Reversible inhibitors bind to enzymes through weak, noncovalent interactions such as hydrogen bonds, hydrophobic interactions, and ionic bonds. The sum of the multiple weak interactions between the inhibitor and the enzyme active site results in strong, specific but still reversible binding [31]. In contrast, irreversible, or mechanism-based, inhibitors cause enzyme inactivation through covalent or quasi-irreversible modification of the enzyme structure. The following sections discuss both classes of inhibition, as well as the meaning of the inhibition kinetic parameters, IC_{50} and K_i .

3.5.1 Reversible Inhibition

3.5.1.1 Competitive Inhibition. The simplest and most commonly observed type of reversible enzyme inhibition is that of competitive inhibition. As the name implies, a substrate and inhibitor are competing for the enzyme active site, and their binding is mutually exclusive. The inhibitor may bind to the same binding region of the substrate or partly mask it. In either case, when the inhibitor is bound to the enzyme, the substrate is unable to bind in a productive orientation and the complex is incapable of catalysis of substrate. Competitive inhibition can be overcome by sufficiently high concentrations of substrate. The kinetic scheme for this type of inhibition is shown in Scheme 3.5.

In case of competitive inhibition, there is no change in V_{max} ; however, an increase in K_m is observed. When comparing inhibition potential of several compounds, it often helps to characterize the inhibition in terms of CL_{int} . Therefore, one can characterize competitive inhibition as resulting in a decrease in CL_{int} (V_{max}/K_m), with no change in the apparent V_{max} . The equation for competitive inhibition is shown in Equation 3.12.

Scheme 3.5

$$v = \frac{V_{\max} \times [\text{S}]}{K_m \left(1 + \frac{[\text{I}]}{K_i}\right) + [\text{S}]} \quad (3.12)$$

In this equation, $V_{\max}$ and K_m have their usual meanings and $[\text{I}]$ is the free inhibitor concentration. K_i is the inhibition constant, and $K_i = [\text{E}][\text{I}]/[\text{EI}]$, which when substituted into Equation 3.12, is in the same form as the Michaelis-Menten equation. From Equation 3.12, it becomes apparent that in the case of competitive inhibition, K_m is increased by a factor $(1 + [\text{I}]/K_i)$ and $V_{\max}$ remains unchanged.

3.5.1.2 Noncompetitive Inhibition. Purely noncompetitive inhibition is rarely observed in enzyme kinetics studies, except in the case of very small inhibitors (e.g., protons, metal ions, and small amides), but is included here for completeness. Noncompetitive inhibition is a form of mixed inhibition where the substrate and inhibitor bind reversibly and independently. In this case, the binding of the inhibitor to the enzyme reduces its activity but has no effect on the binding of the substrate. The kinetic scheme for noncompetitive inhibition is shown in Scheme 3.6.

An example of noncompetitive inhibition would be when the inhibitor binds to the enzyme somewhere other than the active site, thereby changing the enzyme's three-dimensional structure such that the active site is still able to bind substrate but is no longer in the optimal configuration to stabilize the transition state and catalyze the reaction. This type of inhibition results in a decrease in $V_{\max}$ and no apparent change in K_m . On closer examination, most situations originally thought to involve noncompetitive inhibition were actually cases of mixed inhibition. The equation for noncompetitive inhibition is shown below (Eq. 3.13).

$$v = \frac{V_{\max}[\text{S}]}{K_m \left(1 + \frac{[\text{I}]}{K_i}\right) + [\text{S}] \left(1 + \frac{[\text{I}]}{K_i}\right)} \quad (3.13)$$

Scheme 3.6

3.5.1.3 Uncompetitive Inhibition. Uncompetitive inhibition occurs when an enzyme-inhibitor reversibly binds only to the enzyme-substrate (E-S) complex yielding an inactive enzyme-substrate-inhibitor (E-S-I) complex; the inhibitor does not bind to the free enzyme. However, uncompetitive inhibition is also not common. The kinetic model for this type of inhibition is shown in Scheme 3.7.

In this case, the reduction in the effective concentration of the ES complex results in a decreased K_m value and proportional decrease in V_{max} . As a result, the inhibitor has no net effect on V_{max}/K_m (i.e., enzyme efficiency or CL_{int}). The equation to describe uncompetitive inhibition constants, as well as values for K_m and V_{max} , is presented below (Eq. 3.14).

$$v = \frac{\left[\frac{V_{max}}{1 + \frac{[I]}{K_i}} \right] + [S]}{\left[\frac{K_m}{1 + \frac{[I]}{K_i}} \right] + [S]} \quad (3.14)$$

3.5.1.4 Mixed Inhibition. The effects of mixed inhibition on enzyme reactions are such that both specific and catalytic effects are present. As a result, this type of inhibition is characterized by a decrease in the maximal velocity (V_{max}) and an increase in the concentration at which half-maximal velocity (K_m) is achieved. This type of inhibition can be reduced, but not completely overcome, by increasing concentrations of substrate. The kinetic scheme for mixed inhibition is shown in Scheme 3.8, where K_i and K'_i represent the competitive and uncompetitive inhibition components, respectively.

From the kinetic scheme, it is clear that the mechanism that results in mixed inhibition is much more complex than that of others. In mixed inhibition, the substrate can bind to the enzyme-inhibitor complex, which can subsequently dissociate to form an enzyme-substrate complex capable of undergoing catalysis to produce product.

There are multiple binding mechanisms that may account for the observed effects on V_{max} and K_m in the presence of the inhibitor. First, the inhibitor can compete with

Scheme 3.7

Scheme 3.8

the substrate for binding to the enzyme. Second, the inhibitor may bind to an enzyme molecule that subsequently binds to the substrate. Third, the inhibitor can bind to an enzyme-substrate complex and affect catalytic turnover. The effects of the mixed inhibition on the velocity of the reaction can be described by the following equation (Eq. 3.15).

$$v = \frac{V_{\max} \times [S]}{K_m \left(1 + \frac{[I]}{K_i}\right) + [S] \left(1 + \frac{[I]}{K_i}\right)} \quad (3.15)$$

3.5.2 Irreversible Inhibition

3.5.2.1 Mechanism-Based Inhibition. Unlike reversible inhibition that involves rapid association and dissociation of drugs and enzymes, time-dependent inhibition involves irreversible covalent binding or quasi-irreversible tight binding of a chemically reactive intermediate to the heme of the CYP or to the protein itself [32]. In general, a time-dependent inhibitor is defined as a compound that exhibits increased inhibition when incubated with the enzyme before the addition of the substrate. Therefore, mechanism-based inhibitors qualify as a subset of time-dependent inhibitors, in which experimental evidence supports the formation of a chemically reactive metabolite capable of inactivating the enzyme [33].

The *in vitro* characterization of a mechanism-based inhibitor must satisfy seven criteria (see below) and includes the determination of three key parameters: the maximum inactivation rate constant (k_{inact}), the inactivator concentration that produces half-maximal rate of inactivation (K_I), and the efficiency of inactivation relative to metabolism, or partition ratio (r). The necessary criteria defining mechanism-based inhibition include (i) time dependence, (ii) saturation, (iii) substrate protection, (iv) irreversibility, (v) stoichiometry of inactivation, (vi) involvement of a catalytic step, and (vii) inactivation occurring before release of the activated species [34]. The kinetic scheme for mechanism-based inhibition is depicted below (Scheme 3.9), where EI^* is the reactive form of EI , P is the metabolite product, and E_i is the inactivated enzyme. From the model, it is apparent that the enzyme kinetics involving mechanism-based inhibition are complex and are governed by the first-order rate constants k_1 , k_{-1} , k_2 , k_3 , and k_4 [35].

A rate equation representing the loss of functional enzyme with time was described by Kitz and Wilson [36] (Eq. 3.16).

$$\frac{d[E]_t}{dt} = \left(\frac{k_{\text{inact}}[I]}{K_I + [I]} \right) [E]_t \quad (3.16)$$

Scheme 3.9

$[E]_t$ represents the active enzyme concentration at time t ; $[I]$, the inactivator concentration; k_{inact} , the maximum inactivation rate constant; and K_I , the inactivator concentration that produces half-maximal rate of inactivation. From Equation 3.16, it is evident that the rate of P450 enzyme inactivation is proportional to the inactivator concentration and can be saturated at high concentrations [37]. Both k_{inact} and K_I are derived from complex relationships between the first-order rate constants (Eqs. 3.17 and 3.18, respectively).

$$k_{\text{inact}} = \frac{k_2 k_4}{k_2 + k_3 + k_4} \quad (3.17)$$

$$K_I = \left[\frac{k_{-1} + k_2}{k_1} \right] \left[\frac{k_3 + k_4}{k_2 + k_3 + k_4} \right] \quad (3.18)$$

The effects of a mechanism-based inhibitor on the velocity of the reaction can be described by Equation 3.19, where k_{cat} is defined by Equation 3.20.

$$v = \frac{k_{\text{cat}}[E]_t[I]}{K_m + [I]} \quad (3.19)$$

$$k_{\text{cat}} = \frac{k_2 k_3}{k_2 + k_3 + k_4} \quad (3.20)$$

The ratio of the metabolite formation rate to the inactive enzyme formation rate is referred to as the *partition ratio* (r) and is described in Equation 3.21.

$$r = \frac{k_{\text{cat}}}{k_{\text{inact}}} = \frac{k_3}{k_4} \quad (3.21)$$

The partition ratio can be used as a measure of efficiency of the mechanism-based inactivation process, thereby providing useful information regarding the inactivation potential of compounds in early drug discovery.

Experimental conditions employed to determine the kinetics of mechanism-based enzyme inactivation involve evaluation of the time dependence of the reaction. In these experiments, a preincubation (primary incubation) for specific time periods is conducted in the presence/absence of increasing concentrations of the putative inactivator and NADPH, followed by CYP activity measurement by dilution into a secondary incubation [38]. Typical results are depicted in Figs. 3.7 and 3.8.

The half-lives for inactivation of probe substrate at each concentration of inactivator can be calculated from the slopes of the individual lines to give k_{obs} , the pseudo first-order rate constant of inactivation at inactivator concentration $[I]$ (Fig. 3.9). A double reciprocal plot of $1/k_{\text{obs}}$ versus $1/[I]$, known as *Kitz-Wilson plot*, can be constructed to obtain the inactivation parameters k_{inact} and K_I (Fig. 3.9) [36]. In the case of a saturation reaction, the concentration of the inactivator is infinite and there is a finite half-life, and the point where the plotted line intersects the y-axis is equal to $0.693/k_{\text{inact}}$. However, with commercially available graphing software, the inactivation parameters also can be determined by a direct plot of k_{obs} versus inactivator concentration followed by non-least-squares fitting [37].

3.5.3 Context of IC_{50} and K_i Parameters

The parameters of IC_{50} and K_i are used to describe the inhibitory potential of a compound and are routinely determined in early drug discovery to assess the potential inhibition liabilities for new molecular entities. Estimation of K_i follows the same guidelines as for estimating K_m ; multiple substrate concentrations (usually three to four) and multiple inhibitor concentrations (usually four to five) should be used. The range of inhibitor concentrations also should be at least threefold above and below the estimated K_i value [39]. An appropriate definition or specification of the type of enzyme inhibition (e.g., competitive, noncompetitive, mixed) must be selected in order to determine an accurate estimation of K_i . Guidelines for the selection of a proper model have been previously described [37]. However, alternative methods for selecting an inhibition model have been reported [40].

Velocity equations for K_i determinations result in a 3D plot because of the presence of two variable parameters, substrate [S] and inhibitor [I] concentration. Linear transformation of the data, in the form of an Eadie–Hofstee plot (v vs [I]) or as a Dixon plot ($1/v$ vs [I]), allows for easier visualization of the data. The K_i value cannot be determined solely from these graphical representations; however, they are helpful in providing insight into possible inhibition mechanisms involved. In the Dixon plot, for example, if the lines intersect above the x -axis, it suggests competitive inhibition, whereas if the intersection is on the x -axis, it suggests mixed inhibition (Fig. 3.10). To avoid inaccuracies, K_i should always be determined by simultaneous nonlinear regression of the entire untransformed data set using a suitable software program.

In comparison to the K_i value, which represents the dissociation constant of the enzyme–inhibitor complex, an IC_{50} is simply defined as the inhibitor concentration that decreases the biotransformation of a substrate at a single, specified concentration by 50%. The two inhibition parameters cannot be used interchangeably. The IC_{50}

Figure 3.10 Dixon plots showing (a) competitive, (b) mixed, and (c) uncompetitive inhibition.

parameter is dependent on the concentrations of the substrate, inhibitor, and enzyme studied, whereas K_i values are independent of the substrate and thus more readily comparable across laboratories. IC_{50} plots are conventionally plotted as rate versus $\log [I]$, and the resulting curve can be described by Equation 3.22, where v_0 is the control rate, b is the background activity, S is the slope factor, and IC_{50} is the inhibitor concentration that reduces the velocity by 50%.

$$v = \frac{v_0}{1 + \left[\frac{[I]}{IC_{50}} \right]^S} + b \quad (3.22)$$

As with K_i determinations, the IC_{50} value should always be calculated using non-linear regression of the untransformed data.

Owing to the complexity and time-consuming nature of K_i determinations, it is often favorable in drug discovery and development to determine IC_{50} values. The relationship between the K_i and the IC_{50} of an enzymatic reaction is influenced by the type of inhibition (Table 3.1). For example, with competitive and uncompetitive inhibitions, if the IC_{50} determination is made at $[S] \approx K_m$, then $K_i \approx \frac{1}{2}IC_{50}$, whereas for noncompetitive and mixed inhibitions, the IC_{50} and K_i values will be equal [41].

TABLE 3.1 Effects of Various Types of Reversible Inhibition on Kinetic Parameters and the Relationship Between K_i and IC_{50}

Type of Inhibition	Change in Kinetic Parameter by Inhibition			Relationship Between K_i and IC_{50} Values	
	$V_{\max}^{\text{app}}$	K_m^{app}	$V_{\max}^{\text{app}}/K_m^{\text{app}}$	General Equation	If $[S] \approx K_m$
Competitive	$\leftrightarrow$	$\uparrow$	$\downarrow$	$IC_{50} = K_i \left(1 + \frac{[S]}{K_m} \right)$	$\frac{1}{2} K_i = \frac{1}{2} IC_{50}$
Noncompetitive	$\downarrow$	$\leftrightarrow$	$\downarrow$	$IC_{50} = K_i$	$K_i = IC_{50}$
Uncompetitive	$\downarrow$	$\downarrow$	$\leftrightarrow$	$IC_{50} = K_i' \left(1 + \frac{K_m}{[S]} \right)$	$\frac{1}{2} K_i = \frac{1}{2} IC_{50}$
Mixed	$\downarrow$	$\uparrow$	$\leftrightarrow$	$IC_{50} = K_i' \left(\frac{K_m + [S]}{K_m + [S]} \right)$	$K_i = IC_{50}$

3.6 CONCLUSIONS/FUTURE PERSPECTIVES

The determination of enzyme kinetics for drug metabolism reactions is an integral part of drug discovery and development. When carried out carefully and under the proper conditions, one can use these *in vitro* kinetic parameters in making predictions of a drug's potential *in vivo* pharmacokinetics and thus the “druggability” of the compound. Although most compounds follow hyperbolic, saturable (i.e., Michaelis–Menten) kinetics, one can also observe atypical kinetic profiles such as sigmoidal (autoactivation), biphasic, and substrate inhibition kinetics. Thus, it is critical to apply the correct kinetic model to enzyme kinetics data analyses to avoid making inaccurate conclusions about a compound's kinetics. *In vitro* determinations of a drug's potential for drug–drug interactions due to enzyme inhibition are also critical in assessing the potential *in vivo* utility of a compound. Again, one must assure use of the proper kinetic model when assessing propensity to inhibit drug-metabolizing enzymes.

As increasing numbers of compounds are being assessed for their metabolism characteristics during the discovery and development phase, one must continually look to more efficient methods for carrying out these analyses. For example, many high throughput technologies have been applied to ADME (absorption, distribution, metabolism, and excretion) studies such as 96-well-plate automation, parallel LC–MS methods, automated data processing, and sample pooling strategies [42]. Lastly, work will continue toward refining the *in vitro*–*in vivo* correlation models in an effort to better predict human *in vivo* metabolism from *in vitro* data. As we learn more about additional *in vivo* factors that control a drug's rate of metabolism *in vivo* and about intersubject variability in metabolism, these factors can be incorporated into models with the hope of improved predictions.

4.1 SUMMARY

Sex differences in drug metabolism are recognized as a major determinant of sex differences in pharmacokinetics and an important contributor to interindividual differences in drug metabolism and, in some cases, drug action. Historically, sex differences in drug metabolism were widely studied in rat and mouse models in the 1960s and 1970s. Sex differences in human drug metabolism have also been observed with a variety of drugs; however, the quantitative differences in rates of metabolism between men and women are typically much smaller than those seen in rats. The biochemical basis of sex differences in hepatic drug metabolism was largely unknown until the 1980s when it was discovered that expression of some of the drug-metabolizing enzymes, including those in the cytochrome P450 (CYP) family, is sex-dependent in mouse and rat liver. Thus, the expression of certain rat CYP enzymes is male specific (e.g., CYP2C11), whereas others are female specific (e.g., CYP2C12) or female predominant (e.g., CYP2A1). The major gonadal hormones, testosterone and estradiol, regulate the sex-dependent expression of rat hepatic CYP enzymes indirectly through their effects on the hypothalamus and its regulation of the sexually dimorphic, ultradian

rhythm of pituitary growth hormone (GH) secretion, which ultimately dictates the sex-dependent patterns of expression of select CYPs and certain other drug-metabolizing enzymes. In male rats, the intermittent, pulsatile pattern of GH secretion stimulates the expression of male-specific liver enzymes, whereas the more continuous pattern of GH release in females suppresses the expression of male-specific enzymes while inducing female-specific enzymes. Studies conducted in the past decade have identified essential molecular mediators of the effects of GH on sex-dependent liver CYP enzymes and their genes, in particular, the transcription factors—signal transducer and activator of transcription (STAT) 5b and hepatocyte nuclear factors (i.e., HNF4 α). The current view is that STAT5b and HNF4 α coordinately regulate the action of GH and its resultant effect on the sex-dependent expression of hepatic *CYP* genes and thus provide a molecular basis for sex differences in drug metabolism.

4.2 INTRODUCTION

Individual variability in drug metabolism and drug response is well documented in the biomedical literature [1–3]. This variability is manifested as qualitative and/or quantitative differences in drug response within a group of patients (i.e., interindividual variability) or in the same patient (i.e., intraindividual variability). Within a population, patient-specific characteristics such as sex [4], age [5], and genetics [6,7] have been identified as determinants of interindividual variability in drug action. Intraindividual differences in drug action can be induced by administration of a second drug leading to drug–drug interactions, may be caused by deterioration of organ function, or may be by progression in the severity of a disease state, among others [8]. The pharmacological basis for variability in drug response can be attributed to interindividual differences in pharmacokinetics (i.e., drug absorption, distribution, metabolism, and excretion) and/or pharmacodynamics (i.e., the physiological, biochemical, cellular, and molecular actions of a drug). Indeed, patient-specific characteristics are known to influence the biological processes that govern drug absorption, distribution, metabolism, excretion, and functionality of therapeutic targets (e.g., receptors, enzymes) and their associated signal transduction pathways.

Sex differences in drug action were first observed in the 1930s, where adult female rats were found to require only half the dosage of amobarbital (Amytal), as compared to adult male rats, to elicit an anesthetic effect [9], and the duration of action of certain barbiturates (e.g., amobarbital and pentobarbital) was found to be longer in female than in male rats [10]. Subsequent animal and human studies have shown sex differences in the pharmacokinetics and pharmacodynamics of various other drugs [11–15]. Considerably more is known about sex differences in pharmacokinetics, especially sex differences in drug metabolism in the liver than about sex differences in pharmacodynamics. The overall aim of this chapter is to provide an overview of our current understanding of sex differences in hepatic drug metabolism.

4.3 SEX DIFFERENCES IN HEPATIC DRUG METABOLISM

4.3.1 Rat Hepatic Drug Metabolism

Sex differences in hepatic drug metabolism were widely studied in the 1960s and 1970s in experiments involving the incubation of rat hepatic microsomes (liver membrane

preparations enriched in endoplasmic reticulum) with drugs, other foreign chemicals, or endogenous lipophilic substrates (e.g., endogenous steroids and fatty acids). As illustrated in Table 4.1, drugs such as diazepam, lidocaine, and indinavir are metabolized more rapidly by liver microsomes isolated from postpubertal male rats than by those from postpubertal female rats. In contrast, other substrates (e.g., the steroid 5 α -androstane-3 α ,17 β -diol-3,17-disulfate) are more rapidly metabolized by hepatic microsomes from female rats. However, not all substrates (e.g., aniline) exhibit sex difference in hepatic metabolism. Table 4.1 also shows that the sex dependence of drug metabolism can be pathway specific; for example, lidocaine N-demethylation, but not lidocaine 3-hydroxylation, is preferentially catalyzed by hepatic microsomes from male rats. With some drugs, sex differences in hepatic metabolism are strain specific; for example, liver microsomes prepared from BD rats but not those from Wistar rats exhibit sex differences in diazepam N-desmethylation. Sex differences in hepatic drug metabolism may also vary as a function of age (Table 4.1), typically being

manifested during the pubertal and adult periods but not prepubertally [16] and present at a reduced level during senescence [17]. Sex differences in hepatic drug bioactivation can lead to deleterious consequences, as exemplified by the finding that the enhanced N-demethylation of 3,4-methylenedioxymethamphetamine (MDMA, ecstasy) by hepatic microsomes from male rats is associated with an increased susceptibility to the acute toxicity of MDMA, when compared to female rats [18]. In addition to phase I oxidative drug metabolism, sex differences in phase II metabolism affecting glucuronidation, sulfation, and glutathione conjugation, have also been reported in animal studies [19,20].

4.3.2 Human Hepatic Drug Metabolism

Sex differences in human hepatic drug metabolism have been investigated in clinical pharmacokinetic studies that compare the clearance of a drug in men and women. Sex differences characterize the clearance of certain drugs, including cyclosporine [26], erythromycin [27], nifedipine [28], triazolam [29], midazolam [30,31], alprazolam [32], and verapamil [33]. However, in some cases, conflicting data exists with regard to the effect of sex on drug clearance [34–36]. Possible reasons for the conflicting data include (i) the small sample size employed in some of the studies resulting in a lack of statistical power to detect a sex-based difference and (ii) the role of confounding variables, such as age [12,35], ethnicity [37], and other biological determinants of drug clearance, which can include the level of expression of uptake and efflux transporters, although it is debatable whether human hepatic P-glycoprotein expression differs between males and females [38], given the conflicting data in the literature [39,40]. With the increased availability of human hepatic microsomes for research, the *in vitro* metabolism of drugs and other substrates can readily be assessed using microsomes isolated from liver tissue samples obtained from male and female donors. As shown in Table 4.2, in general, sex differences are not apparent or are relatively modest in human hepatic microsomal drug metabolism. An exception is *S*-mephenytoin N-demethylation, whose metabolism is substantively greater in hepatic microsomes from females than in those from males, but this occurs only in samples from Hispanic donors [37]. Overall, sex differences occur in hepatic phase I and phase II drug metabolism, and the differences are generally larger and hence more apparent in rats than in humans.

4.4 SEX-DEPENDENT EXPRESSION OF HEPATIC DRUG-METABOLIZING ENZYMES

The underlying biochemical basis for sex differences in drug metabolism came to light when it was discovered in the 1980s that many of the rat hepatic CYP enzymes (Table 4.3) are expressed in a sex-dependent manner [47]. Since then, sex-dependent expression of other rodent drug-metabolizing enzymes, including UDP-glucuronosyltransferases [48–50], sulfotransferases [49,51,52], and glutathione *S*-transferases [49,53,54], has also been reported. The available experimental evidence suggests that certain human hepatic CYP enzymes may also be expressed differentially in men and women. Overall, among the drug-metabolizing enzymes, the hepatic CYPs are the best characterized with respect to their sex-dependent expression. Thus, the

remainder of this chapter focuses on hepatic CYP enzymes and the various factors that regulate their sex-dependent expression.

4.4.1 Rat Cytochrome P450s

As summarized in Table 4.3, multiple CYP enzymes are expressed constitutively in a sex-dependent manner in rat liver, and their expression is developmentally regulated. Interestingly, a catalytic function of many of these enzymes is the oxidative metabolism of sex steroid hormones such as testosterone. The prototype male-specific P450 enzyme of rat liver is CYP2C11 [55–57, 75]. CYP2C11 is essentially undetectable in both male and female rat liver before puberty, but its expression increases rapidly at puberty (at approximately day 35 of age) in males only and reaches a maximum during early adulthood [58,59]. A similar pattern of postnatal developmental expression has been described for several other male-specific rat hepatic CYP enzymes, that is, CYP2A2 [60,61], CYP2C13 [62], and CYP3A18 [63,64]. In contrast, hepatic expression of the male-specific CYP3A2 is detectable during the prepubertal period in both sexes, whereas at the onset of puberty, the level of CYP3A2 is increased in male liver, but at about the same time it decreases to barely quantifiable levels in females [58]. Another sex-dependent rat hepatic CYP is the female-specific CYP2C12 (Table 4.3). Although CYP2C12 is expressed at low levels in the livers of both sexes prepubertally, its expression is increased at puberty in female rat liver but is suppressed in male rats [58,65]. The female-predominant enzymes CYP2A1, CYP2A7, and CYP3A9 (Table 4.3) comprise a third group of sex-dependent liver P450s. Expression is either similar (CYP2A1

and CYP2C7) or absent (CYP3A9) in both sexes during prepuberty, and the levels of these enzymes are greater in postpubertal female rats than in postpubertal male rats [58,62,64].

4.4.2 Human Cytochrome P450s

In contrast to the rat CYP enzymes, relatively little is known about the sex-dependent expression of human CYPs. With the available information in the literature, many of the conclusions have been drawn from *in vivo* pharmacokinetic studies that measured the plasma clearance of an enzyme-selective substrate (e.g., midazolam for CYP3A enzymes [31]) or urinary formation of a biomarker (e.g., 6 β -hydroxycortisol for CYP3A enzymes [76]). In other cases, conclusions regarding the sex dependence of human enzyme levels have been drawn from *in vitro* metabolism studies (Table 4.2) based on the conversion of an enzyme-selective substrate to its metabolite (e.g., microsomal formation of 6 β -hydroxytestosterone as a catalytic marker for CYP3A [42]). More limited information is available on the immunoreactive protein levels of human CYP enzymes in livers from both sexes. In a panel of 94 liver samples (48 from males and 46 from females), the median level of CYP3A4 was approximately twofold greater in liver samples from females than in samples from males [40]. By comparison, CYP2B6 protein levels were found to be approximately twofold higher in livers from Caucasian women ($N = 15$) than from Caucasian men ($N = 28$), whereas it was approximately fourfold higher in liver samples from Hispanic women ($N = 3$) than in those from Hispanic men ($N = 4$) [37]. In another study of human livers from donors of unknown ethnic origin, multiple linear regression analysis indicated that sex was a

predictor of hepatic CYP2B6 protein levels, but only accounted for 14% of the variance [77]. Overall, it appears that sex differences occur in hepatic expression of human CYP, namely, CYP3A4 and CYP2B6, although the effects are rather modest and considerably less pronounced when compared to the sex differences in the expression of rat hepatic CYP enzymes (Table 4.3).

4.5 HORMONAL DETERMINANTS OF SEX-DEPENDENT EXPRESSION OF HEPATIC CYTOCHROME P450s

A hormonal basis for sex differences in drug metabolism was apparent from early studies showing that (i) castration of postpubertal male rats decreased hepatic microsomal CYP-mediated metabolism of aminopyrine and hexobarbital and (ii) exogenous administration of an androgen (methyltestosterone) fully reversed the suppressive effects of castration [22,78]. These observations paved the way for subsequent studies by various research groups elucidating the hormonal factors that determine the sex-dependent expression of CYP enzymes in rat liver. Collectively, the results of those studies indicate that in addition to gonadal hormones, other hormones also regulate the sex-dependent expression of rat hepatic CYPs. Among these, GH is the most important and the best characterized [79].

4.5.1 Gonadal Hormones

4.5.1.1 Androgen. Androgen has distinct effects on the hepatic expression of the male-specific and female-specific rat CYP enzymes. In male rats, androgen is required for the pubertal expression of the male-specific forms, such as CYP2A2 [60], CYP2C11 [55,58,59,80], CYP2C13 [66], CYP3A2 [58,81], CYP3A18 [82], and CYP4A2 [67], as shown in experiments involving castration of neonatal male rats and exogenous administration of testosterone. Thus, exposure to androgen early in life (e.g., neonatal period) is sufficient to ensure enzyme expression later in adult life in a process known as *neonatal programming* [83]. Full adult expression levels of the male-specific enzymes are achieved in rats exposed to androgen during both the neonatal and peripubertal periods [47]. In contrast to the positive regulation of the male-specific rat hepatic CYP enzymes by androgen, this hormone negatively regulates the hepatic expression of the female-specific CYP2C12, as shown by the decreased enzyme levels in intact, adult female rats administered with exogenous androgen [65,84]. An important conclusion from the available experimental evidence [47,85] is that androgen controls hepatic expression of the sex-dependent rat hepatic CYP enzymes in an indirect manner through its action on the hypothalamic pituitary axis, which results in a sex-specific pattern of pituitary GH secretion (Section 4.5.2).

4.5.1.2 Estrogen. Estrogen also has distinct effects on the expression of sex-dependent rat liver CYP enzymes. In female rats, ovariectomy and exogenous estrogen replacement experiments show that estrogen is required for liver expression of the female-specific CYP2C12 [58,65] and the female-predominant CYP2C7 [80] and CYP3A9 [86]. However, estrogen is not absolutely required for hepatic expression of these enzymes, as these enzymes are still expressed, albeit at low levels, in ovariectomized rats. In intact and castrated male rats, estrogen suppresses the hepatic

expression of the male-specific CYP2C11 [59,80,84]. The effects of estrogen on these sex-dependent CYP enzymes also involves its effects on the sex-specific pattern of pituitary GH secretion [47,85].

4.5.2 Growth Hormone

GH is a 191-amino-acid protein hormone that is secreted by the anterior pituitary gland. Its secretion is rhythmic and episodic over a 24-h period in mammals, including rats [87] and humans [88]. The ultradian rhythm of pituitary GH secretion can be influenced by various factors, including age [89], prolonged food deprivation [90], and sex steroids, particularly, estrogen [91]. There is a distinct sexual dimorphic pattern of GH secretion, which becomes apparent at the onset of puberty [92]. In adult male rats, the plasma GH profile is characterized by well-defined peaks (up to 250 ng GH/mL) and troughs where the levels are very low or undetectable (Fig. 4.1). The period between peaks typically lasts 3–4 h. By comparison, in female rats, GH is secreted in a more continuous manner such as the plasma GH peaks are lower (75 ng/mL), but circulating hormone levels are nearly always detectable (Fig. 4.1).

An initial clue that GH plays a role in regulating hepatic CYP expression was provided by the findings that GH administration decreased total CYP content and hepatic microsomal metabolism of CYP substrates [94]. It is now widely recognized that the sexual dimorphic pattern of GH secretion is the major hormonal determinant

Figure 4.1 Sex dependence of the temporal pattern of plasma GH secretion and hepatic STAT5b activity in male and female rats [93]

^aAs summarized in Ref. 79.^bIntermittent GH administration to hypophysectomized male rats.^cContinuous GH administration of intact male rats.

of the sex-dependent expression of rat hepatic CYPs [47]. On the basis of the available evidence, it appears that the interpulse period devoid of GH is a key signal in the masculinization of CYP expression in rat liver [95,96]. As shown in Table 4.4, the GH-regulated CYP enzymes can be categorized into different classes, based on their response to hypophysectomy [79,127,128]. The expression of a male class I gene (i.e., *CYP2C11*) is decreased in hypophysectomized male rats, whereas it is increased in hypophysectomized female rats but only to a level comparable to that in hypophysectomized male rats. *CYP2C11* levels are increased by intermittent administration of GH and decreased by continuous GH treatment. A corresponding pattern of response is seen for a female class I gene (e.g., *CYP2C12*), except that decreased expression occurs in hypophysectomized female rats and by intermittent GH administration. By comparison, hypophysectomy of female rats increases the expression of class II male-specific genes (i.e., *CYP2A2*, *CYP2C13*, and *CYP3A2*), whereas GH, in particular, continuous infusion of GH in male rats, represses the expression of these genes.

GH regulates the clearance of certain drugs that undergo CYP-mediated clearance [97–99], and also it appears that the sex-dependent pattern of GH secretion controls the expression of human CYP enzymes such as *CYP3A4*, which appears to be expressed at a somewhat greater level in livers from women than in livers from men (Section 4.4.2). As demonstrated in primary cultures of human hepatocytes, continuous GH treatment (to reflect the female pattern of GH secretion) increases *CYP3A4* expression [100,101], whereas intermittent GH administration (i.e., two daily doses, to mimic the pulsatile, male pattern of GH secretion) decreases *CYP3A4* expression, although the effect was

greater in hepatocytes isolated from males than in those from females [101]. The suppressive effect of intermittent GH has also been reported *in vivo*. In a human study conducted in male and female subjects with GH deficiency, GH infusion was associated with an increase in CYP3A activity, whereas GH administered as three daily doses was associated with a decrease in CYP3A activity, as assessed by the erythromycin breath test [102]. In another study conducted in GH-deficient boys and girls, administration of GH once daily for 30 days decreased CYP3A activity, as assessed by the urinary ratio of 6 β -hydroxycortisol/free cortisol, but this response was only observed in boys [103]. Interestingly, the administration of GH by constant infusion over a seven-day period increases CYP3A4 mRNA and protein levels in transgenic male mice [104]. Overall, it appears that the mode of GH administration (intermittent vs continuous) exerts differential effects on human CYP expression in a manner similar to that documented for rat CYP enzymes.

4.6 MOLECULAR DETERMINANTS OF SEX-DEPENDENT EXPRESSION OF HEPATIC CYTOCHROME P450s

Studies in the past decade have increased our understanding of the underlying molecular mechanisms through which GH controls the sex-dependent expression of hepatic CYP enzymes. GH exerts its action by binding to the growth hormone receptor (GHR), which is a member of the superfamily of cytokine receptors [105]. This leads to a conformational change of GHR and activation of a tyrosine kinase known as Janus kinase 2 (JAK2), which catalyzes the tyrosine phosphorylation of various intracellular proteins, including GHR and those belonging to the STAT family, such as STAT5b [106]. The GHR-bound, tyrosine phosphorylated STAT5b dimerizes and translocates to the nucleus where it binds to DNA response elements of target genes and stimulates gene transcription [105,107].

Whereas STAT5b is a direct transcriptional mediator of GH action, GH may also exert indirect effects on gene expression, through various HNFs, including HNF4 α [108], a member of the nuclear receptor superfamily [109]. The available evidence to date indicates that STAT5b and HNF4 α are molecular determinants of the sex-dependent expression of hepatic CYP enzymes [79]. These factors are likely to regulate hepatic CYPs and other sex-specific genes both directly and indirectly, via a complex transcriptional regulatory network, as indicated by the complex time course that characterizes the feminization of these sex-specific genes in male mice infused with GH continuously over a 14-day period [110]. Several other liver-expressed transcription factors show strong sex differences in their expression, including the female-specific factor Cux2 (Cutl2) [111] and the male-specific factor Bcl6 [112]. These factors are both dependent on GH and STAT5b for their sex-specific expression, suggesting that they may play a key role in this transcriptional regulatory network by regulating downstream targets of GH and STAT5b.

4.6.1 STAT5b

A hormonal basis for the tyrosine phosphorylation of STAT5b is provided by the experimental findings indicating that hepatic STAT5b activity is (i) greater in adult

male rats than in adult female rats, (ii) abolished by hypophysectomy, (iii) stimulated by intermittent administration of GH but decreased by continuous administration of GH in hypophysectomized male rats, and (iv) stimulated by continuous GH infusion in hypophysectomized female rats [113,114]. Furthermore, there is a direct temporal relationship between the occurrence of a plasma GH pulse and the activation of hepatic STAT5b activity [115]. As illustrated in Fig. 4.1, in adult male rats, STAT5b is activated by each pulsatile secretion of GH, such that the time for peak STAT5b activity corresponds to the time for peak plasma GH levels and little or no STAT5b activity is detected during the interpulse, GH-free period. In contrast, in adult female rats, there is a very low but persistent level of STAT5b activity over time, similar to the temporal pattern of the low level, continuous release of plasma GH.

STAT5b is essential for the sex-dependent expression of hepatic CYP enzymes and many other sex-dependent genes, as determined in mice genetically deficient in STAT5b. Thus, the sexual dimorphism of hepatic CYP genes is abolished in the absence of STAT5b [116]. As shown in Table 4.5, when compared to the wild-type control male mice, STAT5b-deficient mice have decreased hepatic gene expression of male-specific CYPs (i.e., *Cyp2d9*, *Cyp4a12*, and *Cyp7b1*), but increased levels of female-specific CYPs (i.e., *Cyp2a4*, *Cyp2b9*, and *Cyp2b13*) [110,117]. In female mice, STAT5b deficiency leads to increased hepatic expression of the male-specific *Cyp2d9*, leads to decreases of the male-specific *Cyp7b1*, and has little or no effect on the female-specific *Cyp2a4* or *Cyp2b9* [118]. However, not all sex-dependent CYP genes are regulated by STAT5b because STAT5b deficiency does not influence the hepatic expression of the female-specific *Cyp3a16*, *Cyp3a41*, and *Cyp3a44* [118]. Moreover, hepatic *Cyp2d9* and *Cyp4a12* levels are increased in response to intermittent GH administration in hypophysectomized, STAT5b-expressing male mice but not in hypophysectomized, STAT5b-deficient male mice [110,117]. Collectively, these findings indicate positive regulation of male-specific CYP genes and negative regulation of a subset of female-specific CYP genes by GH pulse-activated STAT5b.

4.6.2 HNF4 α

HNF4 α (gene designation *NR2A1*) is a transcription factor initially known for its role in liver-specific gene expression [120]. It is expressed at high levels in liver and several tissues, and it is constitutively localized in the nucleus [121]. Among its many functions, HNF4 α has been shown to regulate the expression of CYP genes by interacting with various nuclear receptors including constitutive androstane receptor and pregnane X receptor [122,123]. HNF4 α also play a role in hepatic expression of sex-dependent CYP genes [110,124]. As summarized in Table 4.5, HNF4 α deficiency in male mice is associated with a decrease in hepatic levels of the male-specific genes *Cyp2d9*, *Cyp7b1*, and *Cyp4a12*, and an increase in that of the female-specific *Cyp2a4*. By comparison, HNF4 α deficiency in female mice decreases the low level of expression of *Cyp2d9*, whereas it has no effect on the male-specific *Cyp7b1* and *Cyp4a12* and the female-specific *Cyp2a4* and *Cyp2b9*. This pattern of response to HNF4 α deficiency is similar to that of STAT5b deficiency (Table 4.5) and is consistent with the idea that STAT5b is not the sole regulator of the sex-dependent hepatic *Cyp* genes [125,126]. The current view is that HNF4 α functions cooperatively with GH pulse-activated STAT5b to achieve the full expression of male-specific CYP genes [79], a view that is supported by microarray analysis showing global similarities in the dependence of sex-specific genes on STAT5b and HNF4 α in mouse liver [119].

4.7 CONCLUDING REMARKS

Sex differences in hepatic drug metabolism are well documented in rat and mouse models and are increasingly recognized as making a key contribution to sex differences in pharmacokinetics. The underlying mechanisms responsible for the sex differences in the hepatic expression of drug-metabolizing enzymes, in particular, CYPs, are not fully understood but involve complex patterns of hormonal control and intracellular signaling pathways. It is now well established that the sexually dimorphic pattern of plasma GH secretion is a major regulator that controls the sex-dependent expression of CYPs. Studies over the past few years have revealed that sex differences in the liver extend well beyond enzymes of drug metabolism to include more than 1000 genes [127,128], and the transcription factors STAT5b and HNF4 α have been identified as essential determinants of the sex-dependent expression of a large fraction of these genes, including many CYPs. Several other GH-regulated liver transcription factors that show strong sex differences in their expression, as well as a dependence on STAT5b, have also been identified and seem likely to be part of a complex transcriptional regulatory network that regulates the sex-dependent expression of CYPs and many other liver-expressed genes. Much has been learned but much more remains to be elucidated regarding the complex signaling pathways involved in the cellular and molecular actions of GH and how they contribute to sex differences in drug metabolism.

5.1 OVERVIEW

This chapter introduces the reader to the basic differences in drug-metabolizing enzymes (DMEs) between humans and the most commonly employed preclinical animal models. The phenotypic differences in metabolism that are observed between species are rooted in each species genotype; however, it is generally not possible to determine the observed phenotype from the specific genotype. These genotypic differences are largely driven by the different dietary and environmental pressures that each species has been exposed to and ultimately lead to an expressed specific phenotype. This chapter explores both phenotypic and genotypic differences among species in order to give an overview of the many factors that alter the metabolic response between different organisms.

The ability of an organism to respond to the numerous potentially toxic chemicals that it encounters is controlled by a “xenobiotic response,” which can roughly be broken down into two parts, xenobiotic-sensing receptors and DMEs. The xenobiotic-sensing receptors covered here are the aryl hydrocarbon receptor (AHR), the constitutive androstane receptor (CAR), and the pregnane X receptor (PXR). These receptors control the expression of the DMEs that functionally modify xenobiotics in an attempt to detoxify and excrete them from the body. The enzymes covered in this chapter are the cytochrome P450s (CYPs), the uridine 5'-diphospho-glucuronosyltransferases (UGTs), the sulfotransferases (SULTs), and the flavin-containing monooxygenases (FMOs).

Although the overall goal of the “xenobiotic response” is the same for all mammalian species, the systems involved have diverged considerably over time. This divergence has led to differences in the primary genetic sequence of each gene resulting in differences in basal enzyme expression and induction, altered enzyme kinetics and substrate specificity, and ultimately the observed differences in the absorption, distribution, metabolism, excretion (ADME), and toxicity of xenobiotics.¹

5.2 INTRODUCTION

Animal models are commonly used in preclinical drug development to predict the pharmacokinetic and drug metabolism behaviors of new chemical entities (NCEs) in humans. One of the challenges drug metabolism scientists are facing is the extrapolation of metabolic data from animal studies to humans to incorporate into the overall ADME data set. Interspecies differences in drug metabolism have been recognized for many years, with some of the earlier studies investigating the ratio of ortho- to para-hydroxylation of aniline and 1,1'-biphenyl across species. These studies noted differences not only between species but also between different strains of animals, males and females, and the young and old [1–3].

The challenge in predicting human pharmacokinetics and drug metabolism from preclinical animal models is twofold in that there are significant differences in drug metabolism between species (the focus of this chapter) as well as a large amount of variability among human beings due in part to differences in enzyme and receptor expression levels and single nucleotide polymorphisms (SNPs). In order to make an informed decision as to which preclinical species will best predict human drug metabolism, it is important to gain a better understanding of the underlying mechanisms that explain species differences in drug metabolism. These differences are highly related to enzyme (isoform) composition, gene regulation, protein expression, and catalytic activities of the DMEs. The consequences of which can include altered bioavailability, changes in biological half-life, altered prodrug activation, and differential formation of active and/or toxic metabolites [4–7].

This chapter aims to provide the reader with a basic knowledge of the differences between preclinical species for the enzymes most critical in drug metabolism. The most important enzyme system for drug metabolism is the CYP superfamily, in particular, the CYP1, CYP2, and CYP3 families [8–10], and the bulk of the chapter focuses on these enzymes. The UGTs, SULTs, and FMOs are also covered but in lesser detail. Understanding species differences in drug metabolism is helpful for scientists to select the animal models from which the metabolism data can be most accurately extrapolated to humans. Unlike certain physiologic parameters, such as blood circulation and the ratio of organ weight to body weight, for which one can apply an allometric relationship across species in order to predict human pharmacokinetics from preclinical data, no such relationship can be applied to the biochemical parameters that govern the differences seen in the function of DMEs across species [11]. Therefore, it can be generally stated that the more extensively an NCE is metabolized, the more inaccurate

¹For the purpose of this chapter, all gene names for human, monkey, and dog are represented in all-capitalized letters. Gene names for rodents have only the first letter capitalized. Protein names are represented by all-capitalized letters for all species.

the empirical approach of allometric scaling in predicting human pharmacokinetics. In a retrospective analysis, the accuracy of quantitative approaches for the prediction of human pharmacokinetics was determined using 50 compounds for which extensive preclinical data as well as clinical data were available. One of the major conclusions from this analysis was that when a compound was cleared almost exclusively by P450-mediated pathways, scaling from *in vitro* human liver microsome (HLM) data was as predictive as single-species scaling of *in vivo* clearance data from rats, dogs, or monkeys [12].

In order to give the reader an overview of the biochemical basis for the functional differences between the major DMEs that are observed across species, the authors have attempted to focus on four major factors that differ between species for each enzyme subfamily discussed: species differences in inducible enzyme expression, similarity and dissimilarity of primary protein sequence, quantitative and qualitative differences in enzyme expression, and substrate specificity for the metabolism of clinically used drugs and other xenobiotics. The primary protein sequence analysis comes in the form of an accompanying table comparing the percentage amino acid identity for each subfamily discussed in the text (Tables 5.1–5.12). All the amino acid sequences used for the tables were collected from the UniProt database [13] (<http://www.uniprot.org/>), and the percentage homology scores were generated using the ClustalW2 [14] sequence analysis tool from the European Bioinformatics Institute website (<http://www.ebi.ac.uk/Tools/clustalw2/>). Sequences were collected and aligned for human, monkey, dog, rat, mouse, rabbit, guinea pig, and hamster. The tables are limited to sequences that were deposited in the UniProt database and therefore are not representative of every known DME or of every DME discussed in the text. Instead of being all encompassing, these tables are meant as a reference to give the reader an idea of the homology between the different enzyme families and subfamilies at the amino acid level while maintaining consistency with a single database in order to avoid some of the idiosyncrasies that arise during the automated/manual curation of sequence databases by different sources. It should also be noted that the amino acid identity does not necessarily translate into catalytic specificity as a single amino acid substitution is sufficient to alter substrate specificity [15], and many considerations must be made when attempting to determine the appropriate preclinical species for drug metabolism studies. These considerations include differences in the expression levels and inducibility of individual DMEs, tissue- and gender-specific expression, and differences in substrate specificity, as well as factors that may not be related to drug metabolism at all. Turpeinen *et al.* note that if hepatic metabolism were the only factor in choosing a preclinical species, in many cases, the rat is unlikely to be an appropriate model even though it is a very common nonprimate preclinical species; however, it might also be argued that there is no global need for selecting the animal model that is metabolically closest to man. For example, in studies designed for establishing safety margins, one could select an animal model that is likely to result in high amounts of metabolites and potentially improve the safety factors for risk analyses [6].

5.3 SPECIES DIFFERENCES IN ENZYME INDUCTION

Many of the DMEs display inducible expression levels in what is considered an adaptive metabolic response. This inducible expression is governed principally by three

transcription factors: AHR, a ligand-activated member of the Per-Arnt-Sim superfamily [16], and CAR [17] and PXR [18,19], two members of the nuclear receptor superfamily. These three receptors work in concert to alter the expression of a separate but overlapping set of DME genes in response to various xenobiotics. The DME genes controlled by these receptors appear to be relatively consistent across species. The AHR has been historically known as a regulator of xenobiotic metabolism and a mediator of dioxin toxicity but it has also been implicated in many other physiologic roles [20,21]. The AHR is generally associated with the induction of the CYP1 genes, but it is also believed to regulate the expression of some of the UGT1A enzymes [22,23]. Regulation of these genes by the AHR occurs by heterodimerization of the AHR with the aryl hydrocarbon receptor nuclear translocator (ARNT) [24] and by binding to dioxin response elements (DREs) upstream of target genes [25]. Although CAR and PXR seem to be more intimately linked to the overall xenobiotic response than AHR, they have also been implicated in physiologic processes, most notably, the regulation of hepatic energy metabolism [26]. CAR and PXR regulate the expression of many CYP2B, CYP2C, CYP3A, UGT, and SULT genes by forming a heterodimer with the retinoid X receptor (RXR) and binding to a number of different promoter elements upstream of their target genes [27].

Although the battery of DME genes regulated by these receptors is fairly well conserved across species, there are considerable species differences in the ligands that activate the receptors. The ingestion of polycyclic aromatic hydrocarbons (PAHs) and β -naphthoflavone in rat, mouse, monkey, and dog leads to an increase in the level of CYP1A proteins in numerous tissues, such as liver, lung, and intestine [28–30]. The human CYP1B1 gene is also induced by dioxin [31]. Omeprazole has been reported to induce CYP1A2 in man by activating AHR, but the mechanism is not fully understood. The induction of Cyp1a genes by omeprazole does not occur in rat and mouse and is one of the few examples of species-specific activation of AHR [32]. The AHR has also shown considerable species differences in its affinity for dioxin. Guinea pigs show a 1000-fold lower sensitivity to dioxin-induced toxicity when compared to hamster [33]. There are two Ahr alleles in mouse Ahr^b and Ahr^d. The Ahr^d encodes a receptor with 10-fold lower affinity for dioxin [20,34]. The human AHR shows a further 10-fold reduction in affinity for dioxin when compared to the mouse Ahr^d allele [35]. Therefore, the C57BL/6 strain of mice that express the AHR^b enzyme [36] is likely not to be a good model for investigations into human AHR activation.

The nuclear receptors CAR and PXR show a greater degree of alternative ligand binding across species compared to AHR. Phenobarbital is a potent activator of CAR in most species but it does not physically bind to CAR, instead it activates CAR by inducing the translocation of the receptor from the cytoplasm to the nucleus [37]. Lack of binding to CAR is probably the reason why activation by phenobarbital is so well conserved among species. CAR ligands, on the other hand, show a much wider array of effects on the receptor. For example, 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene (TCPOBOP) is a potent activator of mouse CAR but not human or rat [38], 2,4,6-triphenyldioxane-1,3 (TPD) is specific to rat [39], and 6-(4-chlorophenyl)imidazo[2,1-b][1,3]thiazole-5-carbaldehyde *O*-(3,4-dichlorobenzyl)oxime (CITCO) is specific to human [40]. The antifungal clotrimazole is an inverse agonist of human CAR but an agonist of rat CAR [41]. The anti-nausea agent meclizine is also an inverse agonist of human CAR but is a potent agonist of mouse CAR [42]. PXR can bind to a large variety of chemicals because of its large and flexible ligand-binding pocket [43].

Rifampicin is a potent PXR ligand in humans, dogs, and rabbits [30,44,45]. In mice and rats, the prototypical PXR agonists are dexamethasone and pregnenolone 16 α -carbonitrile (PCN) [44,45]. Troglitazone is an activator of human PXR and inducer of human CYP3A4 but does not induce Cyp3a in rodent models or activate rodent PXR [46]. Clotrimazole is an agonist of human, mouse, and rat PXR [41,47], and hyperforin, an active component of St. John's Wort, is an agonist of human PXR but not rat [48].

As discussed in greater detail later, the evolution of adaptive responses to xenobiotics is likely to be greatly influenced by diet. Phylogenetic analyses of CAR and PXR support this hypothesis. CAR and PXR diverged from the chicken X receptor (Cxr) and showed cross talk in the genes that they regulate and the ligands that activate them, creating some redundancy in the expression pathways that regulate DMEs in higher organisms [49] presumably as a means of responding to a larger cadre of exogenous chemicals that these organisms were exposed to. Both of these nuclear receptors show high ratios of nonsynonymous (Ka) to synonymous (Ks) substitutions (the ω -ratio) within their ligand-binding domains when compared to other members of the nuclear receptor superfamily [50]. This ratio is highly suggestive of positive selection for binding to unique ligands and is not surprising when one considers that these two receptors are the most intimately related to the expression of the DMEs most important to xenobiotic metabolism. The high ω -ratio generally equates to rapid evolution and can again likely be traced back to the evolutionary pressure that diet places on this system. In light of this, it is somewhat surprising that there is almost no variation seen in the ligand-binding domains of CAR or PXR among humans [51,52], with most of the SNPs being found within the Japanese population [53,54]. This observation suggests that there are ligands applying negative pressure to the evolution of the CAR and PXR ligand-binding domains in the human population [50]. Phylogenetic analysis of the AHR suggests that ligand binding is a function of the receptor, which arose during vertebrate evolution [20] and has likely developed as a secondary role to the many physiologic processes that the receptor has been implicated in, such as fetal vascular development [55] and cardiac hypertrophy [56].

Further functional differences in these receptors across species can be found in the differential splicing of the primary transcripts. CAR has been shown to generate splice variants in mouse [57] and human [58–62]. The alternatively spliced mouse receptor lacked the ability to bind DNA and did not show any transcriptional or inhibitory properties [57]. A larger number of alternatively spliced CAR transcripts have been described in humans, a few of which have shown functional differences when compared to the reference form of the receptor, including a switch from constitutive activity to ligand-activated activity for CAR2 and CAR3 as well as the ability of CAR2 to recognize unique ligands [63–65]. A number of human PXR splice variants have also been described [66]. The most abundant variant, hPXR.2, is missing 37 amino acids from the ligand-binding pocket and displays significantly diminished ligand-activated transcriptional activity [67,68]. The intronic sequences that signal for the alternative exon splicing do not appear to be well conserved across species, for example, the splice acceptor site for CAR2 has been shown to be conserved across human, rhesus monkey, and guinea pig, but not in mouse, rat, or marmoset [64]. These observations suggest that changes in the genetic code that control pre-mRNA processing are another means by which the diversity of xenobiotic response systems and the ability to adapt to environmental pressures can be increased in a species.

5.4 CYTOCHROME P450s

5.4.1 Overview

The CYPs are hemoproteins that are among the most ancient proteins known and are expressed in almost all living organisms today, from archaeobacteria to humans [69]. They are a fundamental enzyme family for the anabolic and catabolic metabolism of many of the endogenous chemicals required for life and also play critical roles in the biotransformation (bioactivation and detoxification) of a wide variety of xenobiotic chemicals [70,71]. The CYPs are believed to have evolved from a single ancestral gene 3.5 to 4.0 billion years ago [72]. Around 2.8 billion years ago, when oxygen levels began to increase dramatically in the atmosphere, the CYPs likely became involved in the detoxification of oxidative stress [1]. When plants and animals diverged ~1.2 billion years ago, it is believed that an “animal–plant warfare” began, whereby plants evolved toxic or unpalatable compounds to deter animals from eating them and in turn animals evolved new CYP genes to detoxify these chemicals [73]. The “animal–plant warfare” hypothesis is further supported by the observation that there was a large increase in the number of CYP genes following the evolutionary divergence of organisms with a gastrointestinal tract, which led to an increased exposure to xenobiotics from diet [70]. The unique selective pressure that diet places on the animal CYP superfamily and the overall xenobiotic response machinery is likely to be a major evolutionary drive of the functional differences observed between species. This is probably of particular importance for the CYP families 1, 2, and 3, which appear to be most important for xenobiotic metabolism and overall ADME [74], as well as the xenobiotic-sensing receptors that govern their expression.

The CYPs are encoded by a superfamily of genes and exhibit a high degree of structural and functional similarity across a vast array of species. They are localized in the smooth endoplasmic reticulum of the cell and distributed throughout the body, particularly, in the liver, intestine, nasal epithelia, and skin [9,75]. The liver and intestine are the predominate sites for P450-mediated drug elimination and are also a major site of drug–drug interactions (DDIs). The CYPs have been characterized in many species of organisms, including bacteria, fungi, plants, fish, and mammalian systems [76]. There are more than 6500 known CYP enzymes organized into 708 families, of these approximately 2279 among 99 families exist in animals. The approximately 50 CYP enzymes described in man have the most clinical relevance, in particular, approximately the 22 genes in families 1, 2, and 3 that are responsible for the majority of the metabolism of drugs and environmental pollutants [74]. The CYP enzymes from other families are largely involved in endogenous processes, particularly, biosynthesis of hormones, fatty acids, and vitamins [77]. Notably, microbial CYPs are also of clinical importance due mainly to the metabolic capacity that exists in the microflora of the gut. Differences in the composition of these microbes can account for some of the intra- and interindividual differences in drug metabolism and can lead to unexpected metabolic outcomes [78,79]. Gut microflora have been implicated in the metabolism of a number of different drugs including sulfasalazine, sulfinpyrazone, metronidazole, digoxin, isosorbide, flucytosine, and levodopa [1,80].

There are a number of animal species that have been used as preclinical models of drug metabolism; monkey, dog, rat, and mouse see the most widespread use, while rabbit, guinea pig, and hamster are used to a significantly lesser degree. There

are a number of observed differences in the CYPs across these species, including nucleotide/protein sequence, regulation, genetic polymorphism, substrate catalytic specificity, and inhibitor selectivity. 7-Ethoxycoumarin *O*-deethylase (ECOD) activity is catalyzed by several CYP isoforms and can be used as a general measure of xenobiotic-metabolizing capacity [81,82]. This method was applied in an *in vitro* study comparing overall CYP activity between human and several preclinical species, using liver microsomes. The result of the study showed that when compared to humans, ECOD activity was approximately 8.6%, 66.7%, 622%, 1086%, and 508% for mouse, rat, rabbit, dog, and monkey, respectively [6]. This result demonstrates the large range in activity levels that can be found between species and serves as a good example as to why it is valuable to have a good mechanistic understanding of the individual enzymes across species and how they differ in substrate specificity and metabolite formation.

5.4.2 CYP1A

The CYP1A subfamily (Table 5.1) consists of two members, CYP1A1 and CYP1A2. These enzymes have been extensively studied because of their importance in the bioactivation of mutagens and carcinogens. CYP1A activity can be monitored using an ethoxyresorufin *O*-deethylase (EROD) assay [83]. EROD activity in mouse, rat, rabbit, dog, and monkey liver microsomes has been shown to be approximately 374%, 102%, 413%, 630%, and 983%, respectively, of the activity found in humans [6]. The CYP1A enzymes are responsible for the species-specific metabolism of caffeine, where in humans the major metabolite is paraxanthine generated through N3-demethylation. Monkeys generate mostly theophylline by N7-demethylation, while rat and mouse favor C8-hydroxylation to 1,3,7-trimethyluric acid, and rabbits show approximately equal formation of paraxanthine, theophylline, 1,3,7-trimethyluric acid, and theobromine [84].

CYP1A1 is responsible for bioactivation of many environmental carcinogens, such as the PAHs benzo[*a*]pyrene and 3-methylchlanthrene, to highly carcinogenic diol epoxides [85]. The catalytic activities of the CYP1A enzymes are well conserved across mammals. In humans, CYP1A1 is not constitutively expressed (or its basal expression is very low) but is instead expressed only after induction, likely through the AHR pathway [86]. Since CYP1A1 is expressed in very low levels in human liver, the specific activity for the metabolism of PAHs in rodents is more efficient than the activity seen in uninduced human livers [87–89].

CYP1A2 is expressed almost exclusively in the liver of humans, rats, and mice [90,91]. In contrast, monkeys and dogs express CYP1A2 at low levels in the liver in the absence of treatment with an inducer [30,92]. The functional characteristics of CYP1A2 are well conserved across species [4]. In contrast to PAHs, carcinogenic heterocyclic amines are metabolized predominately by CYP1A2 [93,94]. For example, carcinogenic 2-amino-3,8-dimethylimidazol[4,5-*f*]quinoxaline (MeIQx) is metabolized in a species-specific pattern. Rodent CYP1A2 catalyzes both C- and N-oxidation of MeIQx, whereas human CYP1A2 only metabolizes N-hydroxylation at the amine group (a bioactivation pathway to carcinogenicity) [95]. In contrast, the cynomolgus monkey is resistant to MeIQx-related carcinogenicity due to low basal expression levels of CYP1A2 [96]. Therefore, the monkey is not a valuable model for comparison to human.

Human CYP1A2 accounts for 13% of the total liver CYP content and is involved in the metabolism of 4% of drugs in the market, including phenacetin, tacrine, ropinirole, acetaminophen (APAP), riluzole, theophylline, and caffeine. Furaflavone is a selective inhibitor of CYP1A2 in humans, mice, rats, and dogs but is not an inhibitor of CYP1A2 in monkeys. [9,97]. Phenacetin and caffeine have been commonly used as the marker substrates for CYP1A2 in several species. Although there is a strong similarity in amino acid sequence for CYP1A2 and similar catalytic activities toward many drugs have been demonstrated between humans and many animal species, the expression of these enzymes varies considerably among species. For example, dogs and monkeys have low expression levels of the enzyme in the liver and may not serve as good models of CYP1A2-mediated drug metabolism and toxicity in humans in the drug development process [98].

5.4.3 CYP1B

CYP1B1 is the only member of the CYP1B family (Table 5.2). Human CYP1B1 is constitutively expressed in normal tissues, such as lung, liver, heart, brain, kidney, placenta, and prostate [31]. Expression of CYP1B1 is species dependent. Rat Cyp1b1 is expressed in liver and lung, while mouse Cyp1b1 is present in testis, kidney, lung, brain, and heart but not in liver [90,99]. CYP1B1 is differentially expressed within the tumor microenvironment of many cancers, showing much higher expression in tumor cells compared to the surrounding tissues [100,101]. It is also an important factor in determining risk associated with hormone-mediated cancers and catalyzes estrogens to form active 4-hydroxylated derivatives that may cause breast cancer [102]. Similar to CYP1A1, human CYP1B1 and rodent CYP1B1 can bioactivate carcinogenic PAHs to DNA-reactive species associated with toxicity, mutagenesis, and carcinogenesis [103]. Currently, little is known about the activity of CYP1B1 in most preclinical species, and further investigations are necessary.

5.4.4 CYP2A

Table 5.3 shows the percentage amino acid homology for the CYP2A subfamily across species. The human CYP2A subfamily includes CYP2A6, CYP2A7, and CYP2A13. Human CYP2A6 is expressed predominately in liver where it accounts for about 4% of total hepatocyte CYP content [9] but has also been found in the nasal mucosa, trachea, lung, and skin [104,105], while CYP2A13 is mainly expressed in the respiratory

tract [106]. Rat Cyp2a1 (female dominant) and Cyp2a2 (male dominant) are expressed in the liver [107,108], while rat Cyp2a3 is constitutively expressed in the esophagus, lung, and nasal epithelium but is absent in liver [109]. Mouse Cyp2a5 is expressed in the olfactory mucosa, liver, lung, kidney, brain, and small intestine [110]. Cyp2a4 is a predominately female isoform found in mouse liver [111], and mouse Cyp2a12 has been found in the liver but not in the olfactory mucosa [112].

The human CYP2A enzymes show different substrate specificity when compared to the CYP2A of animal species. Human CYP2A6 is involved in the metabolism of a wide range of xenobiotics, including coumarin, nicotine, cyclophosphamide, fadrozole, and aflatoxin B1 [4,113]. Activation of aflatoxin B1 to its carcinogenic/toxic AFB1 (aflatoxin B1)-8,9-epoxide and AFM1 (aflatoxin M1)-8,9-epoxide by CYP2A13 is likely to play a role in the development of lung cancer after aflatoxin inhalation [114]. CYP2A13 is also involved in the metabolism of nicotine and cotinine [115]. Unlike their human orthologs, rodent CYP2A enzymes catalyze the 7 α - and 15 α -hydroxylation of steroids. For example, CYP2A1 is highly specific for the catalysis of 7 α -hydroxylation of testosterone, while CYP2A2 catalyzes both the 15 α - and the 7 α -hydroxylation of testosterone [113,116]. All CYP2A isoforms appear to catalyze coumarin 7-hydroxylation (a marker substrate) but exhibit regioselectivity of the hydroxylation at all six possible positions [117]. Using coumarin 7-hydroxylase activity as a measure of overall CYP2A function [118] in mouse, rabbit, dog, and monkey liver microsomes, it was found that these species had approximately 18%, 8.7%, 2.9%, and 75%, respectively, of the activity found in HLM preparations. In the same study, coumarin 7-hydroxylase activity in rats was found to be below the limit of quantification [6], and in a similar study, it was found to be detectable only when large amounts of substrate were used [119]. This is because in rats, coumarin metabolism occurs mainly through a 3,4-epoxidation reaction catalyzed by CYP2A1 [120]. This regioselective difference in coumarin metabolism between humans and rats also explains the differences in coumarin toxicity between the species; coumarin shows hepatotoxicity and tumor induction in rats because of the epoxide metabolite [117]. In mice, coumarin 7-hydroxylase activity is carried out by CYP2A5 [121] and varies across different strains. The DBA/1J and DBA/2J strains show high 7-hydroxylase activity unlike the C57BL/6J strain that demonstrates low activity at this site [122].

5.4.5 CYP2B

The homology of the CYP2B subfamily across species is presented in Table 5.4. The human CYP2B family includes CYP2B6 and the pseudogene CYP2B7. CYP2B6 is mainly expressed in liver and is involved in the metabolism of a large number of drugs in the market, such as the anticancer drugs cyclophosphamide and tamoxifen, the anesthetics ketamine and propofol, and the procarcinogen aflatoxin B1 [117]. Using pentoxyresorufin *O*-depentylase (PROD) activity as a measurement of overall CYP2B activity [83], it was found that activity in mouse, rat, rabbit, dog, and monkey microsomes was approximately 1000%, 517%, 4827%, 3793%, and 827% of human microsomal activity, respectively [6]. In the same study, using the more specific bupropion hydroxylase assay [123,124], the CYP2B activity was found to be 47%, below quantitation limit, 1084%, 146%, and 605% for the same species compared to humans. The difference in these two assays highlights the large variability that can be seen in the metabolism of different substrates by similar enzymes. The basal expression of

CYP2B6 has been reported to be extremely variable in humans [125–127], and the gene is also highly inducible through the CAR/PXR pathway, making the extrapolation from preclinical species even more difficult.

Mouse Cyp2b9 (female) and Cyp2b10 (male) are sexually dimorphic and lack catalytic activity. The rat Cyp2b subfamily mainly includes Cyp2b1 and Cyp2b2, which have very similar substrate specificities. Both are expressed constitutively in liver and in the extrahepatic tissues, intestine, and lung. Dog CYP2B11 catalyzes the N-demethylation of dextromethorphan, N1-demethylation of diazepam, and the 4'-hydroxylation of mephenytoin [128,129]. Rat, rabbit, and dog CYP2B isoforms all metabolize steroids (androstenedione, testosterone, and progesterone); however, each of these enzymes show unique steroid hydroxylation profiles [130]. 7-Ethoxy-4-trifluoromethylcoumarin and 7-pentoxoresorufin are also metabolized by CYP2B isoforms. K_m and V_{max} values for the enzymes are conserved in liver microsomes across human, mouse, rat, dog, and rabbit species but not in monkey species [7]. Cyclophosphamide, an anticancer prodrug, is activated in the liver by 4-hydroxylation and deactivated by N-dechloroethylation, both of which were observed in rat (CYP2B1) and man (CYP2B6) [131].

5.4.6 CYP2C

The CYP2C subfamily is the largest subfamily and contains multiple isoforms in all species (Table 5.5). In humans, CYP2C isoforms make up ~20% of the total CYP content in liver [132] and are involved in the metabolism of about 16% of drugs in the market [133]. CYP2C8 and CYP2C9 are the major expressed CYP2C forms in humans (>85%), while CYP2C19 expression is low (1%) [134]. Relative to human microsomes, CYP2C activity in mouse, rat, rabbit, dog, and monkey has been found to be 0.6%, 39%, 34%, below the limit of quantitation, and 47%, respectively, by the tolbutamide hydroxylase assay (OH-TOL) [135,136] and 43%, 28%, 50%, below the limit of quantitation, and 172%, respectively, by the omeprazole 5-hydroxylase (5-OH-OME) assay [6,137].

CYP2C8 is expressed mainly in the liver but has also been detected in the kidney, adrenals, and small intestine [138]. It catalyzes the metabolism of retinol and retinoic acid, arachidonic acid, and the anticancer drug paclitaxel (a selective marker) [9,139]. CYP2C9 shows a pattern of expression that is very similar to that of CYP2C8 [138] and metabolizes many clinically important drugs including the diabetic drugs tolbutamide (a selective marker); the anticonvulsant phenytoin; the anticoagulant warfarin; many anti-inflammatory drugs, such as ibuprofen, diclofenac, piroxicam, and tenoxicam; the antihypertensive losartan; the antidiabetic glipizide; and the diuretic torasemide [140]. CYP2C19 is detected in the liver and small intestine [138], is highly polymorphic [141], and has been shown to metabolize *S*-mephenytoin (a selective marker), omeprazole, imipramine, diazepam, barbiturates, and proguanil [9,142–144].

Mouse has more than 10 Cyp2c members. These Cyp2c isoforms have similar catalytic activity in the oxidation of arachidonic acid and hydroxyeicosatetraenoic acids [145]. Among the mouse Cyp2c isoforms, CYP2C37 is the most abundant form in the liver and CYP2C29 is the most abundant in the lung, while CYP2C40 is the major CYP2C found in both kidney and intestine [145–147]. All these enzymes catalyze tolbutamide. The rat Cyp2c family includes at least seven isoforms. They are all expressed in the liver and oxidize dihydropyridines, aflatoxin B1, and steroids [148].

Rhesus monkey CYP2C43, CYP2C74, and CYP2C75 (not shown) display 99% amino acid homology to the cynomolgus monkey CYP2C43, CYP2C20, and CYP2C75 sequences, respectively.

Cyp2c11 (male), Cyp2c12 (female), and Cyp2c13 (male) are gender specific. The dog CYP2C21 and CYP2C41 enzymes are found in the liver, and the latter has been shown to be highly polymorphic. The substrate specificity (tolbutamide, warfarin, and *S*-mephenytoin) of the two dog CYP2C isoforms is impaired when compared to that of humans [149]. Monkey has genes encoding for CYP2C20 and CYP2C43, which are expressed in the liver. CYP2C43, but not CYP2C20, was able to metabolize *S*-mephenytoin, a probe of human CYP2C19, and was not able to metabolize tolbutamide, a probe substrate of human CYP2C9, suggesting that CYP2C43 appears to be functionally related to CYP2C19 [9,150]. Substrate specificities are largely different among the species, particularly, CYP2C forms in dog as a model for human. The stereoselective metabolism of mephenytoin, a marker substrate for CYP2C isoforms shows differences between species. In rabbit, dog, and rat, the *R*-enantiomer is preferentially 4'-hydroxylated two- to sixfold higher than that of the *S*-form. In female mice, both the enantiomers are equally good substrates; and in the rat, CYP2C11 preferentially metabolizes the *S*-enantiomer. However, both human and monkey CYP2C forms preferentially 4'-hydroxylate *S*-mephenytoin with similar K_m values, suggesting that monkeys may be useful as a human model in the metabolism of *S*-mephenytoin [151].

5.4.7 CYP2D

Amino acid homologies for the CYP2D subfamily are presented in Table 5.6. Human CYP2D6, the only active human CYP2D isoform, makes up approximately 1–3% of the total CYP content in the liver and catalyzes the biotransformation of ~30% clinically used drugs. CYP2D6 mainly catalyzes antidepressants (desipramine), β -blockers (propranolol), the antiarrhythmics (sparteine), and dextromethorphan, as well as methadone [152]. Using the dextromethorphan O-demethylation reaction as a selective marker of CYP2D activity [153,154], mouse, rat, rabbit, dog, and monkey microsomes displayed approximately 141%, 96%, 148%, 45%, and 234% of the human microsome activity, respectively [6].

SNPs have been extensively studied in the CYP2D6 enzyme and have been shown to cause a large degree of variability in drug turnover rates for CYP2D6 substrates [155]. CYP2D6 is also known to undergo gene deletion and duplications in humans, a genetic process known as *copy number variation* (CNV), the result of which leads to variable enzyme expression and consequently altered activity [156]. The gene has been reported to be multiplied up to 12-fold in humans, resulting in an ultrarapid metabolizer phenotype [157]. Data on copy number variation of DMEs in preclinical species and what consequences these genetic differences may incur for extrapolations to humans is currently lacking, but it is known that CNVs exist in other species and it appears as though the mechanisms by which they occur are conserved [158]. This issue is further complicated by the fact that the well-documented CYP2D6 SNPs are carried over to the duplicated copies of the gene [159]. The ramifications of CNVs and the combination of CNVs and SNPs on extrapolating drug metabolism data from preclinical species to humans remain unclear and may be very difficult to assess due to conventional laboratory breeding techniques but it is worth noting.

There are as many as nine mouse Cyp2d isoforms but little is known about their catalytic functions. Rats have six Cyp2d isoforms expressed in various tissues, such as liver, kidney, and brain. Cyp2d1 is the likely rat orthologue of human CYP2D6 and shows a similar substrate specificity [160]. Dog CYP2D15 is the major CYP2D form

and also demonstrates enzymatic activities similar to human CYP2D6, such as 1'-hydroxylation of bufuralol and quinidine metabolism [7,98]. Cynomolgus monkey has CYP2D17 an isoform that is 93% identical to human CYP2D6 at the amino acid level. It metabolizes bufuralol and dextromethorphan and is strongly inhibited by quinidine. The marmoset monkey has two known isoforms of CYP2D: CYP2D30 and CYP2D19. Both enzymes have shown regioselectivity of debrisoquine hydroxylation at various positions. A comparison of the CYP2D marker activity, bufuralol 1'-hydroxylation, in liver microsomes of different species showed that rat, mouse, rabbit, and monkey CYP2D6 exhibit a K_m value about 10 times lower than that of human CYP2D6, whereas the V_{max} value is about 6–10 times higher than that of the human enzyme. The kinetic behavior of dog CYP2D15 and human CYP2D6 was shown to be very similar for the catalysis of bufuralol, metoprolol, and dextromethorphan [7].

5.4.8 CYP2E

CYP2E1 is the only member of the CYP2E subfamily (Table 5.7) and is expressed in many tissues such as the nose, oropharynx, lung, and liver. CYP2E1 plays a detoxification role in the metabolism of alcohol to reduce alcohol levels after excessive intake and is also involved in the metabolism of ketones and fatty acids associated with diabetes and obesity [161]. CYP2E1 metabolizes small molecule drugs such as APAP, enflurane, caffeine, and chlorzoxazone (a marker substrate) [162]. In addition to these drugs, some environmental carcinogens and toxicants (benzene, styrene, acrylonitrile, and nitrosoamines) are also metabolized by CYP2E1 to superoxide radicals that cause liver injury and bind to DNA or cellular proteins [163,164]. CYP2E1 is inducible but the mechanism differs from the increased mRNA transcription that occurs after activation of the xenobiotic receptors AHR, CAR, and PXR. Instead, this inducibility occurs through increased translational efficiency and decreased protein turnover [165,166]. CYP2E1 induction by alcohol has been demonstrated in both animals [167] and man [168].

CYP2E1 is known to be highly conserved in mammals [169], and the metabolic pattern of CYP2E1 in humans appears to be very similar to that observed in rodents, and therefore, rodents and rat, in particular, may be an appropriate model to study CYP2E1 in man [98]. In further support of the hypothesis that there is a high level of functional conservation of CYP2E1 across species, it has been shown that in a chlorzoxazone 6-hydroxylase (6-OH-CLZ) assay [170], CYP2E1 activity in mouse, rat, rabbit, dog, and monkey was 150%, 47%, 45%, 45%, and 78% of the average human activity, respectively [6]. This result demonstrates that there is much less variability in chlorzoxazone metabolism than what is generally seen for marker substrates of the other CYP subfamilies. Although chlorzoxazone is considered to be a very good marker substrate for CYP2E1 in mouse, rat, rabbit, dog, monkey, and man, other enzymes have been implicated in its metabolism. Dog CYP1A has been shown to be catalytically active in the metabolism of chlorzoxazone, and human and rodent CYP1A2 may also contribute to chlorzoxazone metabolism [7].

5.4.9 CYP3A

The CYP3A subfamily (Table 5.8) plays a very important role in the metabolism of xenobiotics and catalyzes more than 50% of therapeutic drugs [171], such as

TABLE 5.7 Percentage Amino Acid Homology for CYP2E Subfamily in Various Species

terfenadine, midazolam, diazepam, quinidine, lidocaine, carbamazepine, nifedipine, tacrolimus, dapsone, erythromycin, and dextromethorphan [172]. In addition, CYP3A is also involved in the metabolism of endogenous substances such as steroids, bile acids, and retinoic acid. Human CYP3A enzymes (CYP3A4 and CYP3A5) are expressed in liver, stomach, lung, intestine, and kidney and are the most abundant CYP isoforms in human liver [173]. Using midazolam 1'-hydroxylase (1'-OH-MDZ) as a measure of CYP3A activity [174], mouse, rat, rabbit, dog, and monkey microsomal levels of activity were found to be approximately 103%, 9.2%, 20%, 137%, and 128%, respectively, of the average human activity [6]. Midazolam is a marker substrate of human CYP3A4 and shows significant interspecies variability in metabolism. Higher rates of midazolam 1'-hydroxylation were observed in dogs and monkeys in comparison with human; however, no significant differences were observed between cynomolgus and rhesus monkeys [175].

Mouse has at least six Cyp3a isoforms of which Cyp3a11 is believed to be the orthologue of human CYP3A4. The mouse Cyp3a41 and Cyp3a42 isoforms are preferentially expressed in females [176]. The catalytic activity of the mouse CYP3A toward clinically used drugs has not been extensively evaluated, but it has been shown that some chemicals that are metabolized by human CYP3A4 can be also catalyzed by mouse CYP3A, such as aflatoxin B1 and ethylmorphine [177]. Rats have six Cyp3a isoforms that are expressed in a gender-specific manner. For example, Cyp3a2 and Cyp3a18 are male specific, whereas Cyp3a9 is a female-dominant isoform [178]. Oral bioavailability does not generally correlate well between human and rat forms, and this may be due to higher Cyp3a expression in rat intestine and consequently increased first-pass metabolism [5]. Rats are also not an appropriate model for human CYP3A induction because of the lack of induction response of Cyp3a1/2 to rifampin, a known inducer of human CYP3A [179]. In addition, the metabolism of some CYP3A substrates in rats is different from that in human. For example, nifedipine and dihydropyridine are not metabolized by rat CYP3A [4,10]. The dog CYP3A family has two isoforms, CYP3A12 and CYP3A26. Dog CYP3A has shown similar catalytic activities toward the marker substrates for human CYP3A4 [129,180]. Cynomolgus monkey CYP3A8 is expressed largely in the liver and shows 93% amino acid sequence homology to human CYP3A4 and is identical to rhesus monkey CYP3A64 [181]. CYP3A64 is capable of metabolizing testosterone, midazolam, nifedipine, and 7-benzoxo-4-trifluoromethylcoumarin, which are also substrates for human CYP3A4 and CYP3A5. However, species differences in the CYP3A catalytic activities are observed among rats, rabbits, dogs, and humans.

Testosterone 6 β -hydroxylation is a commonly used marker activity for CYP3A enzymes in all species. There is no significant difference in the reaction among the species, with exception of dogs (higher K_m value) and female rats (higher K_m and lower V_{max} values) [7]. Rats demonstrate a sex-related difference in CYP3A activity. Rat CYP3A not only shows higher rates of the 6 β -hydroxylation than human CYP3A but also generates 2 β - and 16 β -hydroxyltestosterone. On the basis of kinetic similarity in liver microsomes for testosterone 6 β -hydroxylation, mouse and male rat appear to be the most similar species to human. Mouse microsomal testosterone 6 β -hydroxylation is higher in females than in males probably due to the catalytic activity of CYP3A41, a female-specific form [182]. Lidocaine metabolism provides another strong example of interspecies differences in CYP3A metabolism. In humans, lidocaine undergoes an N-deethylation catalyzed by CYP3A4 [183,184]; however, in rats, the major metabolite

is formed through 3-hydroxylation catalyzed by a member of the CYP2D subfamily [1,185]. In general, CYP3A enzymes in all species are involved in the metabolism of xenobiotics and show species-related differences in substrate specificity, expression, induction, and inhibition in various organs and tissues, which together contribute to altered drug clearance, efficacy, and toxicity across species. This wide degree of inter-species variation makes the extrapolation of CYP3A data from animals to man quite difficult.

5.5 GLUCURONOSYLTRANSFERASES (UGTs)

The UGTs catalyze the addition of a glucuronic acid moiety to nucleophilic substrates using uridine diphosphate/glucuronic acid (UDPGA) as a cofactor. The UGT superfamily is composed of a large multiplicity of forms, each with a broad and overlapping substrate selectivity and wide tissue distribution [186,187]. Three major subfamilies responsible for drug metabolism are present to date: UGT1A (Table 5.9), UGT2B (Table 5.10), and UGT2A (Table 5.11). Similar to CYPs, UGTs are localized in the endoplasmic reticulum membrane; however, the active site is exposed on the luminal side of the endoplasmic reticulum, while CYPs are on the cytosolic side [188]. Many endogenous and xenobiotic compounds are able to be glucuronidated by the UGTs. For example, bilirubin and estradiol-3-glucuronidations are selective for UGT1A1, propofol is glucuronidated by UGT1A9, and AZT and morphine glucuronidations occur through UGT2B7. Other endogenous substrates that undergo glucuronidation include bilirubin, estradiol, and other steroids, as well as some fatty acids [189]. UGT1A3 and UGT1A4 are expressed in the liver, intestine, and colon and are the important enzymes in the glucuronidation of many tertiary amine or aromatic heterocycles to form quaternary ammonium glucuronides. The formation of quaternary ammonium glucuronides appears to be highly species specific, with the highest activity being found in humans and monkeys. Rats and mice are generally incapable of forming quaternary ammonium glucuronides because the UGT1A3 and UGT1A4 isoforms are pseudogenes in these rodents. Lamotrigine is extensively glucuronidated at the 2-position of the triazine ring in humans, which represents >80% of the dose excreted in urine. Lamotrigine is not significantly glucuronidated in rats and dogs, while 60% of the dose is excreted in guinea pig urine as the 2-*N*-glucuronide [190]. UGT1A6 is the most important enzyme for the conjugation of planar phenols and amines. It displays high activity for a variety of aromatic alcohols, such as 1-naphthol, 4-nitrophenol, 4-methylumbelliferone, and in the detoxification of APAP. Cats are highly susceptible to APAP liver toxicity because UGT1A6 is a pseudogene in this species [191]. Afloqualone (AFQ) is a centrally acting muscle relaxant, and AFQ *N*-glucuronide is the most abundant metabolite in human urine when administered orally, whereas it was not detected in urine when administered to rats, dogs, and monkeys [192]. Species differences in AFQ *N*-glucuronidation were investigated with liver microsomes obtained from humans and experimental animals. The K_m and V_{max} values of glucuronidation in HLMs were 2.0 mM and 0.87 nmol/min/mg protein, respectively. The V_{max} and intrinsic clearance (CL_{int}) values of AFQ *N*-glucuronidation in human liver were approximately 4- to 10-fold and 2- to 4-fold higher, respectively, than those in rat, dog, and monkey. Both recombinant UGT1A4 and UGT1A3 exhibited high AFQ *N*-glucuronosyltransferase activities.

Expression of the UGT1A gene utilizes different promoters that yield transcripts containing alternative first exons and four identical downstream exons [193]. There is a 93–94% sequence homology in the first exon of human UGT1A7 to UGT1A10, two isoforms that show considerable variation in the level of tissue expression. UGT1A9 is expressed in human liver and kidney, whereas UGT1A7 (esophagus and gastric epithelium), UGT1A8 (intestine), and UGT1A10 (intestine) are expressed extrahepatically. In contrast, rat and rabbit Ugt1a7 are expressed in liver. The rabbit UGT1A7 shows high activity for a variety of small phenolic molecules and imipramine. Rat UGT1A7 catalyzes the glucuronidation of benzo[*a*]pyrene phenols and is inducible by 3-methylcholanthrene. Human UGT1A7 has high turnover for the glucuronidation of 7-ethyl-10-hydroxycamptothecin, an active metabolite of irinotecan, and therefore, may play a role in the gastrointestinal first-pass metabolism of the drug along with UGT1A8 and UGT1A10 [194]. UGT1A8 catalyzes reactions of several drugs including, opioids (buprenorphine, morphine, naloxone, and naltrexone), ciprofibrate, diflunisal, furosemide, phenolphthalein, propofol, raloxifene, 4-OH-tamoxifen, and tolcapone [194]. UGT1A9 is largely responsible for the glucuronidation of a variety of bulky phenols, for example, *tert*-butylphenols and propofol (a marker substrate for UGT1A8 and UGT1A9). UGT2B7 is expressed in the liver and involved in the glucuronidation of non-steroidal anti-inflammatory drugs (NSAIDs), morphine, 3-OH-benzodiazepines, and zidovudine. The glucuronidation of morphine to a pharmacologically active metabolite by human UGT2B7 has been well studied. Morphine-6-glucuronide is much more potent in receptor binding than morphine; however, it has poor permeability and is unlikely to cross the blood–brain barrier. Rats are unable to make morphine-6-glucuronide. UGT2B15 and UGT2B17 are the major forms in human prostate and other tissues such as liver, kidney, skin, brain, mammary gland, ovaries, adipose tissue, and uterus and are responsible for the conjugation of androgens and drugs such as racemic oxazepam [195]. Little has been reported on the species difference of these conjugation reactions.

5.6 SULFOTRANSFERASES (SULTs)

The cytosolic SULTs are derived from a large gene superfamily. SULT1 and SULT2 families are the most important for xenobiotic metabolism. SULTs catalyze the sulfation reactions of many endogenous substances and drugs in the presence of PAPS

(3'-phosphoadenosine 5'-phosphosulfate), providing the sulfuryl donor for the reactions. In humans, the SULT enzyme family comprises 11 isoforms of the SULT1, SULT2, and SULT4 families that code for 10 distinct genes. In humans, SULT1A1 is expressed in the liver and metabolizes sulfation of many known drugs, such as APAP, troglitazone, minoxidil, 4-OH-tamoxifen, and apomorphine. SULT1A3, a catecholamine sulfotransferase, is absent in the adult liver, with the major site of expression being the gastrointestinal tract. This has implications for the metabolism of a number of drugs; for example, salbutamol is almost exclusively sulfated in humans. Human SULT1C2 and SULT1C4 are almost exclusively expressed in fetal tissues, although the function of these enzymes remains unclear. Another important enzyme is estrogen sulfotransferase (SULT1E1), which has a very high affinity (low nanomolar) for its natural substrate 17 β -estradiol and for a major drug substrate 17 α -ethinylestradiol. SULT1E1 is important for modulating estrogen action in the endometrium [196,197]. SULT2A1 plays a selective role in the N-sulfation of quinolone drugs and other amine drugs (ciprofloxacin, moxifloxacin, garenoxacin, desipramine), as well as metoclopramide, pregnenolone, and dehydroepiandrosterone [198]. SULT4A1 cDNAs have been isolated so far from rats, mice, and humans, and the predicted proteins share a remarkable degree of similarity. The SULT4A1 proteins seem to be expressed only in the brain, and despite significant efforts, no natural or xenobiotic substrate has yet been identified [199,200]. Mouse Sult6b1 has been recently cloned and expressed, and it exhibited sulfation activity toward thyroxine and bithionol and a variety of other endogenous and xenobiotic compounds. While human SULT6B1 was specifically expressed in kidney and testis, mouse Sult6b1 was detected in brain, heart, kidney, thymus, lung, liver, and testis [201].

5.7 FLAVIN-CONTAINING MONOOXYGENASES (FMOs)

FMOs are a family of FAD-containing enzymes located in the endoplasmic reticulum. At least five gene products are known to exist in mammals (Table 5.12). The catalytic function of these enzymes involves the oxygenation of soft nucleophilic heteroatoms, including nitrogen, sulfur, phosphorus, and selenium. FMOs catalyze the biotransformation of a wide variety of xenobiotics and endogenous compounds. Human FMO1 has the broadest substrate specificity, particularly for bulky nonpolar lipophilic compounds such as imipramine and orphenadrine, which are selective markers for FMO1 in the kidney. Human FMO3, present in the liver, has a unique property to selectively metabolize small amines, such as trimethylamine. FMO5 is expressed in adult liver and has poor catalytic activity compared to other FMOs. It stereoselectively catalyzes sulfoxidation of short-chain arylalkyl sulfides. Little is reported about the species difference of their catalytic activity. However, the tissue distribution of FMOs in animal species has been reported in rabbits [202]. Rabbit Fmo1 mRNA expression is highest in liver and intestine, Fmo2 in lung, while Fmo3, Fmo4, and Fmo5 are present in lung and kidney. FMO1 seems to be the dominant form in pig and male rat livers. Hepatic Fmo3 expression levels in adult rat and rabbit livers show no gender difference but there is an age-dependent change. In dogs, FMO1 and FMO3 are expressed in liver and lung, with small amounts of FMO3 expression in kidney. There is also a significant gender difference in the hepatic expression of FMO isoforms that exist in mice.

5.8 SUMMARY

In the pharmaceutical industry, the investigation of drug metabolism catalyzed by DMEs in various species is essential for drug development and helps us to understand whether the drug candidates will behave well in humans by demonstrating sufficient efficacy and little or no toxicological liability. Although it is generally believed that data from animal studies can be extrapolated to humans reasonably well with the application of appropriate pharmacokinetic principles, there are certainly some limitations. *In vitro* studies of the DMEs, such as reaction phenotyping, enzyme kinetics, induction, and inhibition, can provide information on the underlying mechanisms and possible prediction of the species differences between drugs and drug candidates in pharmacokinetics, DDIs, efficacy, and toxicity. In addition, the expression level of the enzymes among species responsible for the biotransformation of test drugs is also critical because the metabolic clearance of a drug in the body contributes not only to the catalytic activity of the enzyme(s) but also to the total concentration of the enzyme(s) responsible for the clearance. Therefore, species differences in drug metabolism are attributed to specific activity (product formed per unit time per unit enzyme) for a drug, expression level of the metabolizing enzyme(s), and, in some cases, differences between the inducible expression of the responsible enzyme(s).

The selection of the best animal model to be used in development of a new drug is difficult. Caution should be taken in extrapolation of animal data to humans; however, when *in vitro* metabolism studies with liver microsomes, hepatocytes, liver slices, and recombinant enzymes are available, the information can be incorporated into the decision-making process and can aid in the selection of the appropriate *in vivo* animal model. It is important to remember that it is highly unlikely that any animal model can appropriately model all aspects of drug metabolism for a given NCE, and in many cases, different species may be needed to answer specific questions. Further, as more and more *in vitro* tools are developed, more of these questions are likely to be answered without the use of *in vivo* models, further decreasing the number of animals used in the early drug development process.

The selection of the best animal model to be used in development of a new drug is difficult. Caution should be taken in extrapolation of animal data to human; however, when *in vitro* metabolism studies with liver microsomes, hepatocytes, liver slices and recombinant enzymes are available, the information can be incorporated into the decision-making process and aid in the selection of the appropriate *in vivo* animal model. It is important to remember that it is highly unlikely that any animal model can appropriately model all aspects of drug metabolism for a given NCE and in many cases different species may be needed to answer specific questions. Further, as more and more *in vitro* tools are developed more of these questions are likely to be answered without the needed use of *in vivo* models, further decreasing the number of animals used in the early drug development process.

6.1 SUMMARY

The cytochrome P450 (P450) enzymes are hemoproteins that normally insert one atom of molecular oxygen into their substrates. In mammalian systems, this catalytic process requires the transfer of electrons from NADPH to the P450 enzyme by NADPH-cytochrome P450 reductase (CPR) and/or cytochrome *b*₅. Many alleles exist of both the P450 enzymes and CPR, some of which give rise to major differences in the observed catalytic activity. The human genome contains a family of 57P450 proteins, of which approximately 15 are responsible for oxidative and reductive metabolism of drugs and xenobiotics. The other members of the human P450 family are devoted to the synthesis or processing of steroids, fatty acids, eicosanoids, and vitamins or have functions that are not yet understood. To uniquely identify each of the P450 enzymes, a systematic nomenclature system has been developed on the basis of their degree of protein sequence identity. This system facilitates recognition of the analogies between enzymes of the same or different species.

The crystal structures of several human P450 enzymes have been determined. The structures of these normally membrane-bound mammalian proteins have the same general fold as those of the soluble bacterial P450 enzymes. The spectroscopic properties of all P450 enzymes are similar and can be used to monitor the binding of substrates

to the enzymes. These structural and electronic analogies indicate that the same basic catalytic cycle is involved in substrate oxidation by all P450 enzymes. This consensus cycle involves the binding of molecular oxygen to the ferrous iron of the P450 enzyme followed by reductive cleavage of the dioxygen bond to give a highly reactive ferryl species that directly oxidizes the substrate.

6.2 INTRODUCTION

P450 enzymes are heme-containing monooxygenases that add one atom of molecular oxygen to their substrates while incorporating the other oxygen atom into a molecule of water [1,2]. The overall reaction catalyzed by P450 enzymes can be written as follows, where RH is a substrate and ROH is the product formed by addition of an oxygen atom to it:

A simple example is the conversion of toluene ($\text{C}_6\text{H}_5\text{CH}_3$) to benzyl alcohol ($\text{C}_6\text{H}_5\text{CH}_2\text{OH}$). NADPH is the reducing cofactor for mammalian P450 enzymes, but NADH is the relevant cofactor for most bacterial enzymes. The P450 enzyme in this process is responsible for converting molecular oxygen into a reactive, iron-bound species that can transfer one oxygen atom to the substrate within the enzyme active site. The activation of molecular oxygen and the insertion of an oxygen atom into the substrate are mediated by the heme iron atom. The catalytic cycle, however, requires the participation of auxiliary proteins whose role is to bind NAD(P)H, to uncouple the two electrons provided by this cofactor, and to deliver them singly to the P450 heme group. The auxiliary protein for the mammalian drug-metabolizing P450 enzymes is CPR [3], but two distinct proteins, a flavin reductase (e.g., adrenodoxin reductase) and a ferredoxin (e.g., adrenodoxin), are required for some of the mitochondrial and most of the bacterial P450 enzymes [3].

Genetic analysis has identified thousands of P450 enzymes, and scores of such proteins have been investigated at the biochemical level. This chapter focuses on the human P450 enzymes that are most relevant from the point of view of drug metabolism. Of the 57 P450 enzymes encoded in the human genome (Table 6.1), approximately 28 catalyze critical steps in the biosynthesis or removal of cholesterol, the sterol hormones, the bile acids, the eicosanoids, vitamins, and other physiologically important factors [4]. The P450 enzymes involved in these biosynthetic processes have narrow substrate specificities because evolution has tailored them to process specific endogenous substrates. The reactions catalyzed by such enzymes include removal of the 14α -methyl group of lanosterol in cholesterol biosynthesis [5], cleavage of the cholesterol side chain to generate the 17-keto sterols, progesterone and testosterone [6], and the 10-demethylation and aromatization of testosterone that produces estradiol [7] (Fig. 6.1). Relatively specific P450 enzymes are also involved in the degradation of fatty acids and elaboration of eicosanoids [8,9].

A second subset of approximately 16 human P450 enzymes are primarily involved in the oxidative, and occasionally reductive, metabolism of xenobiotics. This includes most drugs and the broad and variable range of compounds to which an individual is exposed. In most cases, the P450 system introduces an oxygen functionality such as

Figure 6.1 Biosynthetic transformations catalyzed by substrate-specific human P450 enzymes: (a) 14 α -demethylation of lanosterol (CYP51) [5], (b) cholesterol side chain cleavage (CYP11A1) [6], and (c) aromatization of testosterone (CYP19A1) [7].

a hydroxyl or an epoxide into its substrates and can do so even at positions that are chemically difficult to oxidize. A given substrate may undergo multiple P450 oxidations catalyzed by one or several P450 enzymes. The functionalities thus introduced often serve as anchor points for the attachment (conjugation) of sulfate, glucuronide, or other polar moieties. The net result is the conversion of a lipophilic, poorly excreted molecule into a more polar product and finally, after conjugation, into a highly polar, ionic compound that is readily eliminated.

The P450 enzymes primarily devoted to xenobiotic metabolism have broad specificities, in accord with the fact that a small number of enzymes must cope with a

potentially very large and mutable diversity of chemical structures. Their broad specificity means that the enzymes can only exert limited control over both the types of substrates and the sites on those substrates that are oxidized. It is therefore not surprising that P450 enzymes, in the process of oxidizing compounds to more polar and excretable metabolites, sometimes convert a relatively innocuous molecule into chemically reactive and potentially toxic products. Examples of this are the epoxidation of bromobenzene, hydroxylation of phenacetin to give a highly reactive iminoquinone, and hydroxylation of the side chain of chloramphenicol resulting in the formation of an acyl chloride that can either be hydrolyzed by water to the acid or acylate proteins (Fig. 6.2) [10–12].

Some of the sterol hormone biosynthetic enzymes are concentrated in the adrenals, testes, and other steroidogenic tissues [4]. However, the xenobiotic-metabolizing P450 enzymes are not only present in most tissues but also found at particularly high levels in the liver, kidneys, lungs, gut, and nasal passages that are portals for the entry of xenobiotics into the body [4]. All the mammalian P450 enzymes are membrane bound and, with the exception of the seven steroid biosynthetic enzymes that are located in the mitochondria (Table 6.2) [13], are found in the endoplasmic reticulum of the cell. The mitochondrial enzymes are located in the inner membrane on the inner matrix side. The early biochemical work on the mammalian P450 enzymes involved solubilization and purification of the enzymes from native tissues, a historically important approach but one that was ultimately unable to fully resolve and establish the size and nature of the human P450 family. The study of these enzymes has been greatly facilitated by two advances: (a) sequencing of the human genome, which clearly identified the individual members of the family, and (b) the development of *Escherichia*

Figure 6.2 The oxidation of (a) bromobenzene to an epoxide derivative, (b) phenacetin to an iminoquinone that is responsible for the protein alkylation and toxicity associated with this drug, and (c) the oxidative dechlorination of chloramphenicol, which involves the formation of a reactive acyl chloride intermediate.

TABLE 6.2 The Mitochondrial Cytochrome P450 Enzymes and Their Location and Physiological Role

P450 Enzyme ^a	Function	Location
CYP11A (P450 _{scc})	Cleavage of cholesterol side chain to give pregnenolone	Adrenal cortex, gonads
CYP11B1 (P450 _{11β})	11β-Hydroxylation of 11-deoxycortisol to give cortisol	Adrenal cortex
CYP11B2 (P450 _{aldo})	Aldosterone synthesis from 11-deoxycorticosterone	Adrenal cortex
CYP24A1	24-Hydroxylation of 25-hydroxyvitamin D ₃	Kidneys
CYP27A1	27-Hydroxylation of cholesterol	Liver, kidneys
CYP27B1	1α-Hydroxylation of 25-hydroxyvitamin D ₃	Kidneys
CYP27C1	Unknown	—

coli, [14], *Saccharomyces cerevisiae* [15], and baculovirus/insect cell systems [16] for heterologous expression of the individual enzymes [17].

6.3 CYTOCHROME P450 NOMENCLATURE

The human genome encodes 57P450 enzymes (Table 6.1), several of which are considered “orphan” enzymes in that little is yet known about their substrate specificities or physiological roles. The initial nomenclature of P450 enzymes was based on their catalytic and physical properties, including the turnover of specific substrates, the relative migration of the proteins on SDS-PAGE, and their UV–vis absorption maxima. However, this initial nomenclature became unsatisfactory as the number of distinct P450 enzymes increased and related but nonidentical enzymes were found in different tissues and species. A systematic nomenclature was therefore formulated, in which P450 enzymes were classified into families and subfamilies based on the extent of their sequence identity [18]. The hypothesis underlying this approach is that enzymes that are more closely related in sequence, and therefore in evolutionary terms, are likely to exhibit a higher similarity in their catalytic and physiological functions. The basic principle in the new nomenclature is that two enzymes that share 40% or more amino acid sequence identity are grouped within the same family and two enzymes that share more than 55% identity are placed into the same subfamily. The sequence identity values that define the family and subfamily borders are somewhat arbitrary and, to some extent, can be adjusted if required by other evidence. In practical terms, P450 enzymes are assigned a number designating the family, a letter indicating the subfamily, and a second number that identifies the individual protein (Table 6.1). The names can be presented in two formats. One is a historically derived format in which the term P450 precedes the identifying numbers and the second a more systematic name in which the term CYP is similarly placed. Thus, both P4503A4 and CYP3A4 refer to the fourth enzyme of family 3, subfamily A. The name of the gene coding for the protein is the same as the CYP form, except that it is given in italics, that is, *CYP3A4*. In addition

to these systematic names, some of the enzymes that have been studied for many years still have trivial names based on the reactions that they catalyze. Three examples of this are lanosterol 14 α -demethylase (CYP51A1), the cholesterol side chain cleavage enzyme P450_{scc} (CYP11A1), and aromatase (CYP19A1). The terms CYP and P450 are often used as shorthand notations for cytochrome P450.

6.4 CYTOCHROME P450 ABUNDANCE, POLYMORPHISMS, AND VARIABILITY

There are 57P450 enzymes in humans, but the metabolism of drugs and xenobiotics by this enzyme system is primarily mediated by members of the CYP1, CYP2, and CYP3 families (Tables 6.1 and 6.3). The importance of a given enzyme in drug metabolism depends on its distribution within the body, its concentration in specific tissues, and the extent to which its substrate tolerance encompasses the xenobiotics to which it is exposed. In one study of human liver, CYP3A4 (including CYP3A5) accounted for ~30%; CYP1A2, ~13%; CYP2A6, ~4%; CYP2C9, ~20%; CYP2D6, ~2%; and CYP2E1, ~7% of the total P450 content [19]. An immunoquantitation study of human intestinal P450 enzymes similarly found that CYP3A4/CYP3A5 accounted for 82%; CYP2C9, 14%; CYP2C19, 2%; and other forms, 2% of the total [20]. *In vivo*, CYP3A4, the most abundant hepatic and intestinal P450 enzyme, and the closely related enzyme CYP3A5, which cannot be immunochemically distinguished from CYP3A4, account for more than 50% of all P450-dependent drug and xenobiotic metabolism. CYP2C9 and CYP2D6 are each responsible for approximately 15% of xenobiotic metabolism in the liver, and CYP2E1, CYP2C19, CYP2C8, CYP2B6, CYP2A6, CYP1B1, CYP1A2, and CYP1A1 contribute most of the rest [21,22]. However, as summarized below,

TABLE 6.3 Principal Human Cytochrome P450 Enzymes Involved in Drug Metabolism and Examples of Their Substrates^a

Enzyme	Substrates
CYP1A1	<i>R</i> -warfarin, benzo[<i>a</i>]pyrene
CYP1A2	Acetaminophen, bufuralol, caffeine, clozapine, ethoxyresorufin, and theophylline
CYP2A6	Coumarin and nicotine
CYP2B6	7-Ethoxycoumarin and cyclophosphamide
CYP2C9	Benzphetamine, hexobarbital, phenytoin, tienilic acid, and tolbutamide
CYP2C19	Mephenytoin and omeprazole
CYP2D6	Bufuralol, debrisoquine, desipramine, dextromethorphan, propranolol, and sparteine
CYP2E1	Acetaminophen, aniline, caffeine, chlorzoxazone, and halothane
CYP3A4 and CYP3A5	Aldrin, Alfentanil, cortisol, cyclosporin A, dapsone, diltiazem, erythromycin, 17 β -estradiol, ethinyl estradiol, lidocaine, nifedipine, quinidine, sterigmatocystin, taxol, testosterone, and warfarin

^aThis substrate list is drawn from the extensive review of Rendic and Di Carlo [23].

interindividual variations due to genetics, gender, diet, concurrent and prior drug exposure, and environmental factors can alter the relative contributions of the individual P450 enzymes.

The P450 enzymes, to a lesser or greater degree, are polymorphically distributed in the human population (Table 6.4) [4,21,22]. For example, owing to genetic differences, the CYP2D6 activity is relatively low in approximately 7–10% of Caucasians, a difference that decreases the ability of these individuals to oxidize debrisoquine and other compounds that are largely metabolized by this P450 enzyme [24]. Likewise, the concentration of CYP2C19 is relatively low in 20% of the Asian population and 4% of Caucasians, giving rise to an impaired ability to oxidize mephenytoin and other CYP2C19 substrates [25]. Many allelic variants of the human P450 enzymes (>80 for CYP3A4 alone) are now known, some of which do not significantly influence catalytic function but others greatly attenuate, completely suppress, or even increase the activity of a given enzyme. P450 polymorphisms have important consequences for drug metabolism and drug use [26,27].

The majority of drug-metabolizing P450 enzymes are *inducible*, a term that indicates that their concentration can be elevated by exposure to specific chemicals or environmental conditions. Enzyme induction can be the result of a receptor-dependent increase in expression or maturation of the active protein, posttranslational processing of the protein, or a decrease in degradation of the functional enzyme (Table 6.5) [29,30]. For example, CYP3A4 is induced by many drugs including the antitubercular drug rifampicin and the barbiturates, CYP2E1 by ethanol and isoniazid, and CYP1A1 and CYP1A2 by smoking, polycyclic aromatic hydrocarbons, and omeprazole. In animals, most persistent lipophilic substrates cause the induction of one or more P450 enzymes, and this is also true for the human enzymes. Enzyme induction is a temporal

TABLE 6.4 Examples of Some Cytochrome P450 Allelic Variants and Their Frequency in Caucasian and Asian Populations^a

Enzyme	Allele	Activity	Allele Frequency	
			Caucasians	Asians
CYP2A6	*2	Inactive	3	0
	*4	Inactive	0.5	15.1

CYP3A4	Rifampicin, dexamethasone
CYP3A5	Rifampicin

For original literature references see Pelkonen *et al.* [29].

process, as it takes hours to days to fully induce a P450 enzyme and, once the inducing stimulus is removed, results in a gradual return of the enzyme to its resting level. The levels of individual drug-metabolizing P450 enzymes are thus influenced by recent prior exposure to drugs and xenobiotics.

6.5 SPECTROSCOPIC PROPERTIES OF CYTOCHROME P450 ENZYMES

The spectroscopic properties of the heme group, which are sensitive to the nature of the heme iron ligands; the oxidation state of the iron atom; and the polar and hydrogen-bonding nature of the environment around the heme provide important information on the P450 active site [31,32]. The P450 family of enzymes is distinguished from nearly all other hemoproteins by the UV–vis spectrum of their ferrous–CO complexes. While the intense Soret absorption maximum of this complex appears at ~420 nm for most hemoproteins, in P450 enzymes, it is split into two peaks with maxima at ~380 and ~450 nm. The peak at ~450 nm is specifically taken as the hallmark of the P450 enzymes and is the source of the name for this family of proteins. This unique absorption spectrum is due to coordination of a thiolate (RS^-) rather than a histidine or tyrosinate to the heme iron atom [32]. One of the first indications that a P450 enzyme is denatured is a shift of the 450-nm ferrous–CO spectrum to ~420 nm, as this shift signals that the proximal thiolate ligand has been protonated to a thiol ligand or has been entirely displaced from the iron by another functionality [33].

The ferrous–CO spectrum of P450 enzymes defines their spectroscopic signature, but the UV–vis spectra of the ferric enzymes are also informative. In the presence of a distal axial water ligand, the P450 iron atom is in the low spin state and the protein has a Soret absorption maximum at ~416–419 nm. Displacement of this distal water ligand, leaving the sixth iron coordination site vacant, gives rise to a high spin iron with a Soret absorption maximum at 390–416 nm. P450 enzymes can exist as an equilibrium mixture of the high and low spin states, but generally favor the low spin state. The exception to this is provided by enzymes such as CYP1A2 and CYP2D6 that do not appear to have a distal water ligand [34,35]. If the distal water ligand is present, its displacement by a substrate causes a shift in the absorption maximum from

Figure 6.3 Typical difference spectra for the binding of ligands to a P450 enzyme. The spectra shown here are for the binding to bacterial CYP124 of (a) farnesyl pyrophosphate, giving a type I difference spectrum and (b) clotrimazole, giving a type II difference spectrum. In each panel, a spectrum was recorded after each incremental addition of the ligand to the sample cuvette. This figure, based on Ref. 36, was prepared by Dr. Jonathan Johnston.

~419 to 390 nm. This substrate-dependent spectroscopic shift is usually monitored by difference spectroscopy, a technique in which an exogenous ligand is only added to one of two otherwise identical enzyme-containing cuvettes (Fig. 6.3). The resulting difference spectrum, with a maximum at 385–390 nm and a trough at ~420 nm, is known as a *type I binding spectrum* [31]. A different spectroscopic shift is observed if the added ligand coordinates strongly to the heme iron atom, as this gives rise to a difference spectrum with a maximum at 425–435 nm and a trough at 390–405 nm. This so-called type II binding spectrum is observed, for example, when the nitrogen of an imidazole or triazole ring binds to the P450 heme iron atom. A type III difference spectrum with a maximum at 420 nm and a trough at 388–390 nm is obtained if the ligand only coordinates weakly to the heme iron atom. These spectroscopic changes are very useful, as they make it possible to spectroscopically monitor the binding of substrates and inhibitors to P450 enzymes. Exemptions to this approach occur if the resting enzyme does not have a distal water ligand or, occasionally, if the binding of a compound does not displace the distal water ligand.

6.6 STRUCTURES OF THE HUMAN CYTOCHROME P450 ENZYMES

For many years, the only successful crystallizations and structure determinations of P450 enzymes were of the soluble bacterial enzymes. The structure of P450_{cam} (CYP101), the first to be determined, was reported in 1985 [37]. The structure of P450_{cam} and the subsequently determined structures of its complexes and other bacterial enzymes provided a wealth of information, much of which could be extrapolated to the membrane-bound mammalian P450 enzymes. However, 15 years passed before Johnson and coworkers [38] determined the structure of rabbit CYP2C5, the first of a mammalian, membrane-bound P450. The breakthrough represented by this structure has been followed at an increasing tempo by the determination of the

structures of human CYP1A2 [39], CYP2A6 [40], CYP2A13 [41], CYP2B4 [42], CYP2C8 [43], CYP2C9 [44,45], CYP2D6 [46], CYP2R1 [47], and CYP3A4 [48,49], often in the ligand-free state and in complexes with various ligands.

All the P450 enzymes have an approximately triangular prism shape that is dominated by 12 helices (Fig. 6.4) [38–49]. At the center of this structure is an iron protoporphyrin IX (heme) prosthetic group that is held in place by (i) the pincer action of the so-called I and J helices between which it is located, (ii) ion pairing and hydrogen bonds to the two carboxyl groups of the heme, and (iii) coordination of a cysteine thiolate to the proximal side of the heme iron atom. The catalytic action of P450 enzymes depends absolutely on coordination of this cysteine thiolate to the iron atom rather than a protonated cysteine thiol or some other ligand. As mentioned earlier, the ferrous–CO complex of the enzyme with a cysteine thiolate proximal ligand has a Soret maximum at ~450 nm, whereas this absorption maximum shifts to ~420 nm if the thiol is protonated [33]. The distal iron ligand, if one is present, is a water molecule. Given the complexity of the reactions catalyzed by P450 enzymes, there is surprisingly little in the way of catalytic machinery in the active site beyond the thiolate-coordinated heme group. The most important additional catalytic feature is a conserved threonine (or serine) residue on the distal side that (i) helps stabilize the ferrous–dioxy complex through hydrogen-bonding interactions and (ii) through similar interactions, promotes heterolytic cleavage of the dioxygen bond in the [Fe(III)–OOH] intermediate once it is formed. Replacement of this threonine by a non-hydrogen-bonding residue increases decoupling of substrate oxidation from oxygen utilization and results in a decrease or complete loss of substrate oxidation activity. This was first demonstrated for CYP101 (P450_{cam}) [50], but at approximately the same time was found with CYP1A2 to suppress oxidation of benzphetamine but not of 7-ethoxycoumarin [51]. Additional residues, exemplified by Asp251 in P450_{cam} [52], appear to be important in maintaining a hydrogen-bonded network that helps deliver protons to the active site.

On the basis of the crystal structure of CYP101 and an alignment of this P450 sequence with those of the mammalian CYP2 family of proteins, Gotoh proposed that six regions of the mammalian proteins would be involved in substrate binding and recognition [53]. These substrate recognition sequences (SRSs) proved useful in the analysis of substrate binding to the human enzymes before structures for these enzymes became available. The rapidly expanding list of crystallographically determined human P450 structures now provides a more precise structural basis for the analysis of substrate binding and specificity. However, it is increasingly clear that P450 enzymes can undergo both small and large conformational adjustments to optimize the binding of their diverse substrates and inhibitors. Thus, the ligand in the structure of CYP2C9 with warfarin bound in its active site is located at a distance of more than 10 Å from the iron atom, whereas the structure with flurbiprofen in the active site places the substrate much closer to the heme iron atom (Fig. 6.4) [44,45]. The structure of flurbiprofen also

Figure 6.4 The crystal structure of human CYP2C9 in (a) the ligand-free state, (b) with flurbiprofen bound in the active site, and (c) superposition of the ligand-free and flurbiprofen-bound structures. In (c), dark corresponds to the flurbiprofen-bound structure and light color to the ligand-free structure. Flurbiprofen is in very dark tint with the heme below it in dark sticks. Some of the key structural elements of the protein are labeled. The conformational change that occurs on substrate binding is most notable in the F–G loop region. This figure was prepared by Dr. Sylvie Kandel. (See color insert.)

differs from that of the protein without a bound ligand, a difference most clearly seen in the F–G loop region of the protein (Fig. 6.4). The CYP2C9 protein in these two crystal structures is found to have undergone substantial conformational alterations. A second example is provided by the unligated structure of CYP2B4, which exhibits an open access channel into the active site [42]. A second structure with the protein complexed with 4-(4-chlorophenyl)imidazole shows the ligand in the active site close to the heme, with the access channel closed by the shift of a domain of the protein [54]. The dynamic plasticity of the P450 active site confounds efforts to understand and predict substrate specificity based on the limited set of human P450 crystal structures that are currently available.

6.7 ELECTRON-DONOR PARTNERS: CYTOCHROME P450 REDUCTASE AND CYTOCHROME b_5

Two electrons are required for each successful oxidation of a substrate by a P450 enzyme. In the case of the human drug-metabolizing forms of P450, these electrons are provided by CPR and/or cytochrome b_5 (Fig. 6.5) [55]. CPR is a 78-kDa protein with a hydrophobic N-terminal sequence that anchors it to the endoplasmic reticulum membrane. In contrast to the multiplicity of P450 enzymes, there is only one form of CPR. As shown by the crystal structure [56], the protein contains one FMN and one FAD that are used to uncouple the electrons provided by NADPH in order to deliver them one at a time to the P450 heme group. The enzyme is specific for NADPH and is not significantly reduced by NADH. The FAD group, reduced by hydride transfer from

Figure 6.5 The catalytic cycle of most cytochrome P450 enzymes, including all of those involved in human drug metabolism. The iron in brackets represents the P450 heme iron atom; RH, a substrate; ROH, its oxidized product; and XOOH, a peroxide. The upper part of the cycle represents productive turnover in which the substrate RH is oxidized. In the lower part, turnover can also become uncoupled from substrate oxidation, producing superoxide, H_2O_2 , and/or a second molecule of water. CPR, cytochrome P450 reductase; Cyt b_5 , cytochrome b_5 .

NADPH, transfers electrons to the P450 heme group via the FMN prosthetic group. With two flavin groups, CPR can accept up to four electrons, two for each flavin, but catalytic turnover usually involves cycling between the one- and three-electron reduced forms. Although truncated forms of CPR obtained by limited digestion of the endogenous membrane-bound enzyme or heterologous expression are able to reduce cytochrome *c*, they are no longer able to effectively reduce P450 enzymes. CPR, like the P450 enzymes themselves, is subject to polymorphic expression [57]. These polymorphisms are associated with disorders such as Antley–Bixler syndrome, the result of a perturbation of sterol hormone synthesis, but also have implications for drug metabolism [27]. Interestingly, CPR variants can interact differently with different P450 enzymes, so that the influence of a given CPR allele on one P450 enzyme cannot be extrapolated to another P450 enzyme [27].

With many P450 enzymes and substrates, electron transfer from CPR alone is sufficient to obtain maximum P450 catalytic turnover. However, with some enzymes, including CYP3A4, substrate oxidation can be enhanced or even modified by electron donation from cytochrome *b*₅ [58,59]. Cytochrome *b*₅, which can itself be reduced by either NADH/cytochrome *b*₅ reductase or CPR, is generally unable to deliver the first electron required to initiate P450 catalytic turnover [59]. However, it can deliver the second electron required to complete the catalytic cycle. One effect of cytochrome *b*₅ is therefore to enhance coupling of the electrons for the formation of the P450-activated species, an improvement that is achieved by decreasing the futile, uncoupled reduction of O₂ to H₂O₂ or water. Cytochrome *b*₅ may also influence P450 catalysis by allosteric mechanisms independent of its own electron-transfer ability, as illustrated by the finding that CYP3A4-catalyzed testosterone 6 β -hydroxylation and nifedipine oxidation are stimulated by apocytochrome *b*₅ [58,60] and by the fact that cytochrome *b*₅ serves as a physiological control that helps determine which of the two possible products of sterol oxidation are formed by the sterol 17-hydroxylase/lyase (CYP17A1) [61].

6.8 CYTOCHROME P450 CATALYTIC CYCLE

The catalytic cycle of P450 appears to be the same regardless of whether the enzyme is from bacteria, plants, insects, or humans. Because the bacterial P450 enzymes are soluble and often more stable than their membrane-bound mammalian counterparts, much of the detailed work on the P450 catalytic cycle has been carried out with bacterial enzymes, particularly, CYP101 (P450_{cam}). However, a large body of the evidence obtained with the mammalian P450 enzymes confirms that the core mechanism of these enzymes is essentially invariant. As the high spin form of P450 enzymes is more easily reduced than the low spin form, catalytic turnover is initiated by the binding of a substrate, which displaces the distal water ligand if it is present (Fig. 6.5). In bacterial CYP101, the redox potential shifts from $E_{1/2} = -300$ to -170 mV upon binding of camphor, bringing the P450 within the range accessible to putidaredoxin, the electron-donor partner, which has a redox potential $E_{1/2} = -196$ mV [62]. Although a similar correlation of spin state with redox potential was initially not apparent for the mammalian enzymes reconstituted in artificial lipid mixtures [63], recent studies of CYP3A4 embedded in a more physiological nanodisc environment have given results consistent with those for CYP101 [64]. In these studies, substrate-free CYP3A4, which is 11%

high spin, was found to have an E° of -220 ± 10 mV, but the redox potential shifted on binding of erythromycin (22% high spin, $E^\circ = 210 \pm 10$ mV), testosterone (92% high spin, $E^\circ = -140 \pm 5$ mV), and bromocriptine (93% high spin, $E^\circ = -137 \pm 5$ mV). Electrons are transferred to these protein complexes by the FMN domain of one of the multiple oxidation states available to CPR [65].

Once the enzyme is reduced to the ferrous state by the first electron transfer, molecular oxygen binds to yield the ferrous–dioxy complex $[\text{Fe(II)}-\text{O}_2]$. This complex, unlike the analogous complex of myoglobin or hemoglobin, is not stable and, in the absence of further catalytic action, reverts to the ferric enzyme by the loss of superoxide. In the coupled catalytic cycle, however, the ferrous–dioxy complex is further reduced by a second electron from an electron-donor partner to the ferrous–peroxy complex $[\text{Fe(III)}-\text{OO}-]$. This intermediate is rapidly protonated to give the ferric hydroperoxide $[\text{Fe(III)}-\text{OOH}]$. The P450_{cam} peroxy anion and hydroperoxide complexes have been observed spectroscopically at low temperatures [66]. Heterolytic cleavage of the dioxygen bond in the ferric hydroperoxide, which requires the uptake of a second proton and loss of a water molecule, produces a ferryl intermediate [1,2]. This ferryl intermediate is two oxidation states higher than the resting ferric state. It can formally be written as $[\text{Fe(V)}=\text{O}]$, $[\text{Fe(IV)}=\text{O}]$ with a porphyrin radical cation, or $[\text{Fe(IV)}=\text{O}]$ with a protein radical, but the favored formulation appears to be $[\text{Fe(IV)}=\text{O}]$ coupled to a porphyrin radical cation. This formulation is the same as that for the “Compound I” activated species of horseradish peroxidase, although the proximal iron ligand in that enzyme is a histidine nitrogen [67]. Efforts to detect the P450 “Compound I” ferryl intermediate, including cryogenic X-ray studies [66], have been tantalizing but ambiguous. However, recent investigations at the low temperature in which the reactive intermediate is generated by photoirradiation of a chemically generated $[\text{Fe(IV)}=\text{O}]$ precursor provide strong support for its formulation as an $[\text{Fe(IV)}=\text{O}]$ /porphyrin radical cation [68,69]. This ferryl intermediate is held to be the species that is directly responsible for most substrate oxidations.

Although the ferryl intermediate mediates most of the oxidation reactions, in a few P450 reactions, the ferric peroxy anion $[\text{Fe(III)}-\text{OO}-]$ adds as a nucleophile to a carbonyl group, resulting in cleavage of the carbon–carbon bond between the carbonyl group and the parent structure [2]. A classic example is the 14α -demethylation of lanosterol, in which the enzyme (CYP51) oxidizes a methyl group first to an alcohol, then to an aldehyde, and in a final reaction involving the $[\text{Fe(III)}-\text{OO}-]$ intermediate removes the carbon atom as a molecule of formic acid (Fig. 6.6). It has also been proposed that the ferric hydroperoxy intermediate $[\text{Fe(III)}-\text{OOH}]$, in addition to serving as the precursor of the ferryl species, may itself oxidize some substrates. This intermediate, which is an electrophilic rather than nucleophilic oxidant, could conceivably oxidize thioethers, amines, olefins, and other easily oxidized functions. However, the evidence for a role of the $[\text{Fe(III)}-\text{OOH}]$ intermediate in substrate oxidation remains unclear, as most of the evidence in favor of such reactions is derived from studies of mutants designed to impair the ability to form the ferryl intermediate (e.g., 70). This compromises the evidence because the role of the ferric hydroperoxide intermediate will depend on the relative rates of its conversion to the ferryl species versus its direct reaction with the substrate. Nevertheless, although its participation in hydrocarbon C–H bond oxidation is highly unlikely, it may yet prove to contribute in some situations to the oxidation of more easily oxidized functionalities.

Figure 6.6 The three steps in the oxidative demethylation of lanosterol catalyzed by CYP51A1. [Fe(III)–OO–] represents the P450 ferrous peroxy anion intermediate.

An important parameter in P450 catalysis is the degree of uncoupling of oxygen consumption from substrate oxidation. As already indicated, the catalytic cycle traverses intermediates in which the heme iron atom is formally coordinated to a superoxide ion [$\text{Fe(II)}-\text{O}_2 \leftrightarrow \text{Fe(III)}-\text{O}_2^{\bullet-}$] or a hydrogen peroxide anion [$\text{Fe(III)}-\text{OOH}$]. Dissociation of these ligands can result in the formation of superoxide or H_2O_2 , respectively, as the aborted products of P450 catalysis. Furthermore, there is evidence that the ferryl intermediate can itself be reduced by two electrons to a water molecule, regenerating the resting ferric enzyme. The importance of these uncoupling reactions depends on the specific P450 enzyme, the specific substrate, and the intervention or not of cytochrome b_5 .

In vitro, many P450 enzymes can turn over their substrates with H₂O₂ rather than NADPH/CPR as the supporting system in what is termed the *shunt pathway*. In most cases, alkylhydroperoxides can be used instead of H₂O₂. In a sense, the mechanism of the P450 reaction with H₂O₂ is the reverse of autooxidation pathways, as the reaction is thought to generate the [Fe(III)–OOH] intermediate involved in normal catalytic turnover. The shortcoming of the “shunt” pathway is that peroxides readily damage the heme group and inactivate the enzyme, so that catalytic turnover can be fairly short-lived. It is unlikely that H₂O₂-dependent turnover of human P450 enzymes occurs to a significant extent *in vivo*, but the use of this approach *in vitro* has proven of value in investigating the mechanisms and specificities of the enzymes.

6.9 CONCLUSIONS

The P450 system is amazing in that by and large it can cope with the enormous variety of compounds to which mankind is exposed, particularly if one considers that only a dozen or so actual proteins are involved. A consequence of this metabolic efficiency is that highly reactive metabolites that are toxic or carcinogenic are not infrequently produced. The requirement for an efficient substrate oxidation system to enable the elimination of lipophilic xenobiotics thus carries with it the inherent potential to damage the host. This yin–yang balance is increasingly found in biology: one only

has to consider the cases of superoxide, nitric oxide, and carbon monoxide to find additional examples of biological two-edged swords.

7.1 INTRODUCTION

Most drugs are metabolized in the body, and understanding these processes is critical to the evaluation of pharmacokinetic suitability and their potential for toxicity and drug interactions. A generation ago, the lack of suitable human pharmacokinetic properties was the major cause of attrition of new chemical entities in the pharmaceutical industry [1]. Today, the fraction of failures due to poor pharmacokinetic properties is much lower (~8% [1]), and the change can be attributed in large part to our improved understanding of the human enzymes involved in drug metabolism, including the transporters.

The fraction of drug metabolism reactions (i.e., for all drugs) attributed to P450s is ~75% (Fig. 7.1) [2,3]. Of the 57 human P450 (*CYP*) genes, 5 account for 95% of drug metabolism [2,3]. In many cases, more than one P450 may be involved in the metabolism of a drug, even catalyzing the same reaction. The point should be made here that each P450 has the potential to catalyze many, if not all, of the types of reactions that discussed in this chapter because of the universality of the chemical mechanism.

The metabolism of a drug must be characterized in humans before it can be introduced into the market. The regulatory requirements have been made more stringent with the implementation of the Food and Drug Administration Guidance on Metabolites in Safety Testing in the United States [4], with similar International Conference on Harmonization guidelines now in place. Understanding metabolism, particularly, P450 reactions, is also important in considering and stratifying new chemical entities in pharmaceutical development, especially when there are issues regarding pharmacokinetics,

drug interactions, and safety issues. Knowledge of P450 reactions may be critical in understanding the nature of glutathione (GSH) and macromolecular adducts and their implications.

7.2 OVERVIEW OF P450 REACTIONS

Before discussing the details of the P450 reactions, it is useful to consider the overall P450 cycle and which steps are most relevant to considerations in drug metabolism. A generally accepted scheme is shown in Fig. 7.2, although it must be emphasized that (i) the scheme shows only an electronic view of the reaction cycle (focused on the iron atom), without the changes in protein conformation that are known to be associated with various steps; (ii) some of the steps may have multiple steps within them (e.g., substrate binding); and (iii) this is not necessarily a linear cycle, for example, substrate may enter or come off at various states, not only at a single one.

The P450 cycle begins with the P450 iron in the ferric form. In step 1, the substrate binds. Such binding may or may not change the spin state or the oxidation–reduction potential. Step 2 involves the transfer of an electron from the flavoprotein NADPH-P450 reductase. This protein and the reaction have been studied extensively, and the system is not discussed here [5–7]. The ultimate source of the electrons is from NADPH, which transfers a hydride ion (two electrons) to the diflavin reductase, and the electrons flow through FAD to FMN to P450, necessarily one at a time. The rate of electron transfer to a P450 may or may not be enhanced by the presence of the substrate [8].

Step 3 involves the addition of O_2 to the ferrous iron. The resulting complex is unstable, and the rate of decomposition varies among P450s [9]. Step 4 involves the transfer of an electron to the ferrous–oxy complex ($Fe^{2+}O_2$). This can occur from NADPH-P450 reductase, although it has been much more difficult to study this reaction

Figure 7.2 General catalytic cycle for P450 enzymes.

than step 2, so the nature of the electronic states is less secure. Cytochrome b_5 (b_5) can enhance some P450 reactions and has been shown to transfer an electron at this stage [10,11]. (Electron transfer from b_5 to P450 is possible at step 2—the difference in oxidation–reduction potential makes the rate slow [12].)

Following step 4, the reactions have been even harder to observe, and still much of our understanding of these steps is based largely on work with biomimetic models and, to some extent, theoretical considerations. The current understanding is summarized in Fig. 7.2. The FeO_2 complex can be depicted as $\text{Fe}^{2+}\text{O}_2^-$ and abstracts a proton; evidence exists that this is achieved via a Thr-based proton network in the I-helix [13,14]. As discussed later, there is speculation that the FeO^{2+} and FeOOH^{3+} complexes can be the oxygenating species. However, (in the author's opinion) the current bulk of evidence supports the view that homolytic scission of the O–O bond to yield the FeO^{3+} complex (step 6) is a critical step in most P450 reactions. The FeO^{3+} complex has a strong precedent in peroxidase chemistry as “Compound I”. However, attempts to characterize this intermediate in P450 have been difficult and controversy exists regarding exactly how stable it is [15–17]. In none of these reports has the intermediate been shown to form a product using unambiguous methods. Despite these experimental deficiencies, the FeO^{3+} complex is considered in all the mechanisms presented. The designation FeO^{3+} is used to avoid assigning electronic distribution to the iron atom, the oxygen, the porphyrin, and the Cys thiolate ligand (to the iron). The most common view of the electronic distribution is $\text{Fe}^{4+}\text{O}_2\text{-porphyrin radical}^+$.

Step 7 involves hydrogen abstraction (or one-electron oxidation) by the FeO^{3+} complex, yielding FeOH^{3+} (Compound II, electronically equivalent to FeO_2^{2+}) plus a radical. In general, these radicals do not accumulate in P450 reactions as they do in peroxidase reactions. The rate of “oxygen rebound” (step 8) is considered fast

and estimated to be $\sim 10^{10} \text{ s}^{-1}$ [18]. However, in some cases, rearrangements (of the substrate radical) are fast enough to occur and thus detect the steps.

The final step is release of the product to complete the reaction cycle. In general, most products seem to have affinities similar to the substrates.

7.3 P450 REACTIONS AND MECHANISMS

7.3.1 Substrate Binding

Substrate binding (step 1) is important in that the juxtaposition of the substrate in the P450 is critical to the reaction course, that is, the regio- and stereoselectivity, as well as the rate. Until recently, the nature of the P450 active sites was a matter of speculation or homology modeling based on a few bacterial P450s. Since 2003, structures have been obtained for the five human P450s most involved in drug metabolism—1A2, 2C9, 2C19, 2D6, and 3A4 [19–24] (2C19, Johnson EF, personal communication)—as well as for 2A6, 2A13, 2C8, 2E1, 2R1, 17A1, 19A1, 21A2, 46A1, and 51A1 [25–33]. The active sites vary considerably in size, from 190 to 1385 Å³ (for 2E1 to 3A4, respectively) [23,27–29,34]. Just as importantly, the shapes of the active sites and various binding forces contributed by individual amino acids influence the binding of substrates. To elaborate on this last point, the size of the P450 2C8 active site is as large as that of P450 3A4 [23,34] but the shape is less “open,” which may contribute to the narrower list of substrates. An example of how individual residues are involved is seen in P450 2D6 and the negatively charged amino acids Asp-301 and Glu-216 that interact with amine ligands [35–37]. The point should also be made that the shapes (and sizes) of the active sites are variable and change as the P450 binds different substrates, as judged from the crystal structures available to date. Thus, there is evidence that some aspect of induced fit occurs in substrate binding. However, the binding of ligands is clearly not so universal that every substrate can be bound by every P450.

One issue beyond the scope of this chapter is cooperativity. Cooperativity can be either homotropic or heterotropic. Homotropic cooperativity involves atypical interactions of the same substrate (or ligand), yielding positive or negative cooperativity for either binding or catalytic activity, for example, sigmoidal kinetics. Heterotropic cooperativity involves interaction of two different ligands and the ability of one to enhance the binding or catalytic activity of the other (*in vitro*, without any involvement of enzyme induction). These interactions are generally considered to involve two ligands within the active site of a P450, although few experiments have been done to eliminate the possibility of interactions due to binding at distant sites. In two cases, there is crystallographic evidence of multiple occupancy of a ligand in a human P450 [29,38], and some fluorescence evidence for direct interactions has also been reported [39].

Most P450s have the substrates imbedded in their interiors and must undergo conformational changes to open and close each time a ligand enters or exits. Some P450s can be described in a two-state system, either bound (with ligand) or unbound, and interchange is rapid. For instance, P450 2A6–coumarin binding can be characterized with a k_{on} of $2.7 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ (in the range of diffusion-limited reactions of proteins) and k_{off} of 5.7 s^{-1} . Thus, P450 2A6 must open and close for more than five times every second (at 23°C). Similar kinetic parameters were measured with the product 7-hydroxycoumarin [10].

Studies with P450 3A4 [40,41] and (rabbit) P450 1A2 [42] have provided evidence for a different course. The initial rate of interaction of ligands with these P450s is fast, as demonstrated by the rate of decrease in the fluorescence of the ligand α -naphthoflavone (α NF). However, the changes in the heme iron spin state are one to two orders of magnitude slower and follow a biexponential course [40]. Our interpretation is that the substrate binds rapidly at a site of the periphery (explaining the α NF quenching) and then moves slowly into the active site of the heme, in a position for catalysis (Fig. 7.3). The course of the events is slow enough to overlap the oxygenation process [40] and then complicate the kinetic analysis.

One explanation for biexponential kinetics of substrate binding is the existence of two or more distinct structural populations of unbound P450, for example, one in a boundlike structure (poised for binding) and a second structure (“ground state”), which are in slow equilibrium and bind substrate at different rates. In the experiments with the P450s 1A2 and 3A4 [40–42], results from pulsed mixing and other techniques argue against this explanation. However, the possibility of such phenomena cannot be dismissed for other P450 systems.

When P450s open and close to allow ligands to enter and leave, or (as in the cases of P450s 1A2 and 3A4) to migrate within the enzyme, particular residues along the “access” channels may be involved in the interactions. At this time, postulates of these mechanisms are only speculative. Given the similarities of drug substrates and products of P450s (i.e., often the products are substrates for further oxidation), a strong case cannot be made for the existence of separate entrance and exit channels.

Finally, regarding practical significance of these issues, the point should be made that predicting metabolism is still difficult. Several bioinformatic strategies have been useful (e.g., MetaSite, Sporcalc, Glide, and Dock) [43], although most success has been achieved with systems based on prior experience with similar compounds as opposed to basic principles of chemistry and structure. Clearly it is more useful to have P450

Figure 7.3 A proposed scheme for movement of a ligand into the active site of a P450, based on work with the P450s 1A2 and 3A4 [40–42]. L, ligand.

structures than not, but making predictions is still not trivial. As an example, the structure of the human P450 1A2- α NF complex [19] has the site of epoxidation positioned farthest from the iron [42]. Substrates can bind P450s in multiple ways, only some of which will be productive.

7.3.2 The Nature of the Active Oxygen

In early research on P450, the question of the nature of the active oxygenating species was a matter of interest. Much of the early discussion involved mobile elements such as superoxide anion ($O_2^{\cdot-}$) or some sort of an oxene species that could achieve the observed reactions. Such discussions were stimulated by evidence that NADPH-P450 reductase could generate $O_2^{\cdot-}$ [44]. While some findings supported this hypothesis [45], there were at least two major problems: (i) $O_2^{\cdot-}$ is nucleophilic but the nature of P450 reactions requires an electrophilic reagent and (ii) such a mechanism provides no control of regio- and stereoselectivity (or, in fact, even a role of the heme other than possibly reducing oxygen to a diffusible form).

Work in the area of biomimetic models suggested that a more appropriate model might be an electrophilic iron-oxygen complex [46], a view that developed further with metalloporphyrin models [47–49]. Another seminal study [50] showed that P450 reactions were associated with high intrinsic kinetic deuterium isotope effects and scrambling of stereochemistry, both of which could be interpreted as indicative of a reaction involving a radical intermediate. Further, typical P450 reactions occurred when P450 was mixed with single-oxygen donor “oxygen-surrogates” such as iodosylbenzene [51,52]. Thus, the view emerged that the P450 mechanism involves a course of events such as those shown in Fig. 7.4.

The P450- FeO^{3+} complex is electronically similar to peroxidase Compound I, which can catalyze some of the same reactions as P450s. The peroxidase Compound I is much more stable and has been extensively characterized, existing as an Fe(IV) ($=O$) complex with a one-electron deficiency in the porphyrin ring. The reduction of horseradish peroxidase Compound I occurs with $E_{m,7} \sim 1.0$ V, and the same $E_{m,7}$ has been estimated for the reduction of Compound II (of horseradish peroxidase) [54]. Similar values have been measured for biomimetic model metalloporphyrins [55,56]. A potential cannot be measured for the unstable P450- FeO^{3+} entity, but modeling and Marcus theory considerations suggest an even higher potential [57].

Although the perferryl FeO^{3+} species satisfies many criteria as the P450 oxygenating agent, alternate proposals have been developed and should be mentioned (Table 7.1). One unusual P450 reaction is the third step of the P450 19A1-catalyzed conversion of androgens to estrogens, involving the conversion of an exocyclic formyl group into formic acid and insertion of a double bond into a ring [58]. Model compounds have been shown to undergo similar deformylations [59–61]. One mechanism developed to explain this involves the $FeOO^-$ intermediate attack on the aldehyde [62]. Subsequent work with model P450 oxidations has led to the proposal that this reaction might be more general in P450 reactions [63]. Peracids are known to epoxidize olefins, and even flavin 4a-hydroperoxides are now known to be involved in some epoxidations [64]. The possibility exists that some of the more facile P450 oxidations can be catalyzed by the $Fe^{2+}O_2(H)$ entity (Table 7.1). However, three points should be kept in mind: (i) theoretical considerations have been used to argue against a role of $Fe^{2+}O_2^-$ or $Fe^{2+}OOH$ in C-hydroxylation and epoxidation [65];

Carbon hydroxylation**Heteroatom release****Heteroatom release****Epoxidation and group migration**

Figure 7.4 Generalized mechanism of P450 oxidation, based on FeO^{3+} chemistry [53].

(ii) many of the arguments for a role of Fe^{2+}O_2 in reactions rely on mutants in which the active site Thr was converted to Ala to disrupt protonation of the $\text{Fe}^{2+}\text{O}_2^-$ entity, but the interpretation of these active site mutants, as is often the case, may not be unambiguous; and (iii) even the aromatase deformylation step (see above) can be rationalized by a radical mechanism, which has some favor on theoretical grounds [66].

Alternate mechanisms have been proposed to explain apparent inconsistencies in “radical clock” experiments, that is, the lack of rearrangement of some molecules before the oxygen rebound [73]. The lack of rearrangement leads to very short estimates of

TABLE 7.1 Potential Iron–Oxygen Complexes Involved in P450–Catalyzed Oxidations^a

the lifetimes of intermediates (e.g., 10¹³ s^{−1} [74]), which are considered closer to transition-state lifetimes than intermediates. However, studies with other radical clocks have led to more consistent values for intermediate lifetimes [18]. The point should also be made that the strained cycloalkanes used as radical clocks may not necessarily undergo the same rates of ring opening inside the proteins (due to binding) as in solution and therefore lead to unusual values in some cases [75].

In part to explain some of the discrepancies in the radical clock results, Shaik has developed a two-state theory to explain alternate reactions that both proceed from a given substrate (Table 7.1) [68,76]. This is a theoretical system and has not been addressed in “wet” experiments. Details of the theory are beyond the scope of this chapter, but in short, the proposal has high and low spin configurations of the iron in the same FeO³⁺ entity, leading to different products. The proportions of high and low spin FeO³⁺ are a function of not only the P450 but also the substrate. Therefore, each system would have to be calculated (and the effort in calculation with a significant part of the protein is considerable in each case), so developing testable predictions is not trivial.

7.3.3 Considerations of Rate-Limiting Steps

In considering a particular P450 reaction, one question is which step (Fig. 7.2) is rate limiting. Associated with this is the even larger question of what really drives regioselectivity of reactions, beyond spatial and thermodynamic considerations. Some considerations are also in order regarding kinetic deuterium isotope effects, which may have new relevance in drug design [77].

In Fig. 7.2, step 1 has not historically been considered rate limiting, but the newer studies on the rates of movement into the active site with some P450s suggest that this aspect should be reevaluated in some cases [40]. Step 2, the reduction, has often been evaluated. It may be rate limiting in some cases [8], in that addition of extra reductase may stimulate some reactions [78,79]. Step 3 (O₂ binding) is not generally thought to be rate limiting, although in some cases P450s reduce substrates instead of oxidizing them, implying that the substrate competes effectively with O₂ for binding to ferrous iron.

Step 4 is often considered to be rate limiting because of the stimulatory effect of *b*₅. This appears not to be an artifact of the reconstituted system, in that anti-*b*₅ can also inhibit microsomal reactions [12]. However, electron transfer may not be the issue

[80–82]. If an electron is not transferred rapidly, the FeO_2^{2+} complex will dismute to ferric iron and $\text{O}_2^{\cdot-}$.

Little direct information is available on how rate-limiting step 5 is, in that this step cannot be measured. Site-directed mutagenesis can lower the rates of P450s, but these results do not provide an insight into rate limitation with wild-type P450s. Obviously, the complex will dismute if forward progress is attenuated. All of this discussion also applies to step 6.

Step 7 usually involves the breaking of a C–H bond and therefore is the only step amenable to interrogation by kinetic isotope experiments (except $^{18}\text{O}_2$ activation [83]). In numerous cases, kinetic deuterium isotope effects are seen and provide evidence that step 7 is the rate-limiting step, at least sometimes.

Step 8, oxygen rebound, has already been discussed. The rates are fast and do not limit the overall rate at which the P450 cycle (Fig. 7.2) operates, but the rate at which a radical intermediate rearranges will influence the distribution of products.

The final step (step 9) is product release. There are two ways of estimating this rate. One is to measure the apparent rate of product binding as a function of (product) concentration and extrapolate to zero concentration to obtain the off-rate. This experiment only works with a relatively low K_d . The other approach is to look for burst kinetics in a pre-steady-state kinetic experiment, with a burst indicating that the step following product formation is rate limiting [84]. Our own work has demonstrated the lack of rate limitation of step 9 in certain reactions catalyzed by the P450s 1A2 and 2A6 [10,85]. In the cases of oxidation of ethanol and acetaldehyde by P450 2E1, nearly quantitative bursts were observed [86,87]. However, considerations regarding the binding of acetaldehyde and acetic acid indicate that this slow step is probably a conformational change (undefined) instead of actual product release.

The point should be made that the concept of a rate-limiting step is too simplistic in a complex reaction cycle such as the P450 cycle (Fig. 7.2). The overall rate of product formation is limited not only by the forward rates of each step but also by the reverse rate constants, when reversible, and particularly by the rate of “side” pathways, for example, the loss of substrate at any of the several early points [10] and the formation of $\text{O}_2^{\cdot-}$, H_2O_2 , and H_2O [10,88].

Some more discussion of kinetic isotope effects is in order, given the number of published studies and the confusion often attached to them. Most P450 reactions involving direct C–H bond breaking show appreciable intrinsic isotope effects, in the range of 3 to as high as 20 or more [85,89]. The intrinsic isotope effects are usually estimated using noncompetitive intramolecular experiments (with consideration of possible secondary isotope effects) or indirect approaches such as Northrop’s method [90] or “branching analysis” [91]. Whether or not C–H bond breaking is rate limiting depends on the isotope effect measured in a noncompetitive intermolecular experiment, in which the (k_{cat}/K_m) parameter measured with a protiated substrate is divided by that measured with a deuterated substrate, with appropriate considerations (high fraction deuterium in deuterated substrate, no inhibitory impurities). This ratio is termed $^D(V/K)$, and the ratio of the two k_{cat} values is $^D V$ [90]. If these values approach the intrinsic isotope effect, then there is strong evidence for rate limitation. Obviously, if other steps are rate limiting then the isotope effect will not be expressed.

These considerations are important in light of recent interest in preparing deuterated versions of drugs to enhance pharmacokinetic properties [77]. Deuteration may or may not produce an isotope effect *in vivo*. Some drugs have produced *in vivo* isotope

effects [92]. One issue *in vivo* is which parameters to assess; the most useful are probably $C_{p, \max}$ (maximum extrapolated plasma concentration) and clearance, which is related directly to the area under the curve (AUC). N-Dealkylations (of amines, not amides) generally show low kinetic isotope effects, because of their mechanisms, and the strategy would be less useful. To date, there has been no clear distinction as to which P450s show isotope effects, so phenotyping of the reaction if of little guidance.

7.3.4 Mechanisms of Oxidation of Major Reactions

The groupings of reactions will be slightly different than in previous reviews from this laboratory. With P450 oxidations covering thousands of different drug substrates and reactions, memorizing them all is impossible and, as in teaching organic chemistry, the only solution is to teach these in logical sets. Using the approach of teaching from chemical mechanism also provides a sound basis for the learner to deal with rather unusual reactions that seem too complex to discern at first observation.

Drug metabolism is best taught—in the author's experience—like organic synthesis, in that one starts with the product and then considers ways to work backward at each step, considering what is known about P450 (and other) reactions. One must appreciate nonenzymatic changes such as carbinolamine breakdown and ring formations. Starting to solve a complex biotransformation pathway by working forward is like designing a synthesis this way from crude materials—there are too many possibilities—so it should be worked backward. Of course, drug metabolism scientists may be called upon to predict possible transformations, but the likelihood of certain reactions happening is always difficult and experience is useful in this regard (particularly experience with similar compounds).

7.3.4.1 Carbon Oxidations (sp^3). The basic paradigm was discussed earlier (Figs. 7.5 and 7.6). The FeO^{3+} abstracts a hydrogen atom, and then oxygen rebound completes the reaction. A few variations on this theme follow.

In O-dealkylation of ethers (Fig. 7.5a), a similar hydroxylation occurs to yield a hemiacetal, which hydrolyzes. The same type of reaction can occur with esters, yielding an aldehyde and carboxylic acid [93] (Fig. 7.5b).

Another mode of the C–H cleavage is desaturation (Fig. 7.5c). This process is agreed to start with hydrogen atom abstraction. Instead of direct oxygen rebound, either a subsequent abstraction of the vicinal C–H atom or a nonenzymic rearrangement could occur to generate the vicinal radical, and the $FeOH^{3+}$ entity could abstract ($H\cdot$) again at the original site. Either process would have the same stoichiometry and yield the desaturated product plus two molecules of H_2O . Desaturation reactions are usually accompanied by some alcohol formation, suggesting such a bifurcated pathway, but in at least one case desaturation appears to be extensive, without alcohol formation [94]. With ethyl carbamate, the subsequent epoxidation was much faster than desaturation and special methods were needed to quantify the olefin [95].

7.3.4.2 Heteroatom Oxidations (N, S, P, I). Most of this section applies to nitrogen, and the rest is applicable to sulfur and the other heteroatoms that often appear in drug heterocycles, and so on.

N-Dealkylations are considered to occur either by the hydrogen abstraction pathway described or, when the distance and oxidation potential are appropriate, by initial one-electron abstraction (Fig. 7.6). The aminium radical is unstable and, after α -proton

Figure 7.5 Carbon oxidation. (a) Oxidative cleavage of an ether, (b) oxidative cleavage of an ester, and (c) bifurcation between C-hydroxylation and desaturation reactions.

Figure 7.6 N-Dealkylation mechanism based on initial one-electron oxidation, and rearrangement of the resulting aminium radical.

abstraction, rearranges to a carbon radical for incipient oxygen addition, followed by breakdown of the carbinolamine. The FeO^{2+} is basic and helps abstract the α -proton, a mechanism not available in many peroxidases [96,97].

Several lines of evidence support the view that P450s N-dealkylate by the above pathway (although they are not excluded from hydrogen atom abstraction). (i) The low intrinsic kinetic deuterium isotope effects are consistent [97,98]. (ii) With dihydropyridines (which are vinylogous analogs), 4-alkyl groups are released and can be trapped as radicals (Fig. 7.7a) [99]. (iii) Other compounds with low oxidation potentials undergo characteristic rearrangements diagnostic for radical cations, for example, quadricyclane [100], or radical cations can be directly observed (e.g., 1,2,4,5-tetramethoxybenzene [101]). (iv) Rearrangements and mechanism-based inhibition with strained cycloalkylamines are observed and consistent with aminium radical formation [102–104]. (v) Analyses by Hammett and Marcus approaches are consistent with an aminium radical mechanism [57,105].

Figure 7.7 Two types of evidence in support of a one-electron transfer pathway (Fig. 7.6). (a) Oxidation of a 1,4-dihydropyridine with a 4-alkyl substituent leads to the extrusion of alkyl radical, which can be trapped, while oxidation of a 4-aryl analog yields to the retention of the 4-position moiety [99,106]. (b) Oxidation of *N*-ethyl-*N*-methylaniline by rat P450 2B1 yields a 20-fold excess of *N*-demethylation over the *N*-deethylation product [107].

Following abstraction of one electron, the resulting aminium radical rearranges to a carbon-centered radical. There is evidence that the FeO^{2+} (Compound II) entity acts as a base to facilitate this process [97]; most peroxidases only abstract electrons via the heme edge [96] and as a result are not capable of dissipating the aminium radicals and rebounding oxygen.

A similar process can be proposed for S- and P-dealkylations, in that the redox potentials are generally accessible. The point should be made that amides do not have low one-electron oxidation potentials, and therefore, N-dealkylation reactions of amides probably proceed largely via hydrogen abstraction. The higher kinetic deuterium isotope effects are consistent with this view [108].

Another point to be made is that the effective oxidation–reduction potential, $E_{(\text{app})}$, is a function of the intrinsic potential, $E_{(\text{int})}$, and the interatomic distance ($r_{1,2}$, in Å), as well as the dielectric constant (D).

$$E_{(\text{app})} = E_{(\text{int})} + \frac{14.4}{r_{1,2}D} \quad (7.1)$$

Thus, how far the nitrogen (or other heteroatom) is from the FeO^{3+} entity and the protein local dielectric constant influence the oxidation potential of the substrate.

Another experiment strongly implicating one-electron mechanisms is the N-dealkylation of *N*-ethyl-*N*-methylaniline by P450 2B1 [107], in which the ratio of N-demethylation to N-deethylation was 20:1, consistent with the higher stability of a methyl aminium radical but not with the inductive effect expected for methylene hydrogen atom abstraction [98] (Fig. 7.7b).

Oxygenation of heteroatoms is also observed with P450s. Two mechanisms can be considered. One is a one-electron oxidation, as discussed earlier (Fig. 7.8). This mechanism is intellectually satisfying in that it couples the different types of oxidations that occur with nitrogen and sulfur molecules and explains why oxygenation

Figure 7.8 Proposed N-oxygenation proceeding via one-electron oxidation.

is usually a very minor reaction when dealkylation is possible [105]. Even when N-dealkylation is favored, some N-oxygenation occurs, and the generally greater tendency of sulfur atoms to undergo oxygenation (rather than S-dealkylation) is consistent with greater radical stability. Interestingly, N-dealkylation of a series of substituted *N,N*-dimethylanilines yields a Hammett plot with a negative ρ value, consistent with stabilization of an aminium radical intermediate [105] but no such relationship was seen for N-oxygenation [107]. An alternate mechanism involves a direct transfer of oxygen to the heteroatom, without one-electron chemistry. Conceivably, this might even happen with $\text{FeO}_2(\text{H})$, as proposed [109], instead of FeO^{3+} (Table 7.1). The point should be made that another microsomal monooxygenase, FMO, is prominent in the oxygenation of nitrogen and sulfur atoms [110], and care is needed to discern whether P450 or FMO is involved.

In heteroatom oxygenation, most of the focus is on nitrogen and sulfur, two atoms that often have low oxidation–reduction potentials. In general, the high oxidation potential of oxygen makes an electron-transfer pathway less likely, and most of these reactions proceed by the carbon hydroxylation pathway described earlier. Phosphorus oxygenation is known [111] and very feasible due to the low oxidation potential. Other heteroatom oxygenations involve halogens, as first proposed for dihaloethanes [112]. An iodosylbenzene-dependent oxygenation of iodobenzene was demonstrated by Burka *et al.* [113]. NADPH-dependent P450 oxygenation of aryl iodides and bromides was demonstrated later [114] using model compounds that trapped the resulting haloso products to yield stable entities. Although chlorine is harder to oxidize, He *et al.* [115] demonstrated that ω -chloro and ω -bromo fatty acids are oxygenated (on the halogen) by rat P450 4A1 (The products are unstable, and the analysis was based on the detection of isotopically labeled (^{18}O) alcohols, with the oxygen being derived from H_2O and not O_2 .)

7.3.4.3 Reaction of π -Bond Substrates. This class includes mainly olefins, acetylenes, and aryl compounds. The bulk of the evidence is consistent with a stepwise mechanism in which FeO^{3+} reacts with a double bond to generate an intermediate, with a radical localized at the carbon vicinal to the C–O bond formed (Fig. 7.9). An epoxide can be formed by a hemolytic mechanism. Alternatively, electron transfer can generate a carbocationic intermediate. This intermediate could also close to form an epoxide, in a heterolytic process, or undergo a 1,2-shift of an anion (e.g., halide or hydride ion [116]) to generate a rearranged carbonyl product. In the case of aryl compounds, the aryl ketone rearranges to generate a phenol. This process is a part of the so-called NIH Shift (of hydrogen or other atoms) [117]. The point should be made that the demonstration of an NIH shift in the formation of a phenol is not definite evidence for the existence of an epoxide intermediate in the process; the mechanism may occur without the epoxide (Fig. 7.10).

Similar mechanisms can be written for the oxidation of acetylenes, with the collapse of an intermediate via a heterolytic path to form a putative epoxide [118], hydrogen

Figure 7.9 Some possible mechanisms of oxidation of olefins and acetylene.

Figure 7.10 Aromatic hydroxylation and an NIH shift of a *para*-hydrogen [117] via two mechanisms: (a) concerted epoxidation followed by rearrangement and (b) stepwise electrophilic attack followed by rearrangement.

migration to generate a (reactive) ketene, or direct reaction with the heme porphyrin to generate an adduct (Fig. 7.9).

The view that a common mechanism drives these reactions is consistent with a number of lines of evidence and supported by kinetic hydrogen isotope effect results [119]. Thus, the mechanism can be considered to be nonconcerted. Another phenomenon that has been observed with some P450s and some of their substrates is proton exchange with water during epoxidation, which can only be explained with an intermediate involving a Fe–C bond [120]. However, an alternate point of view is that dual mechanisms are involved in the two-state system of Shaik [68]: a concerted low spin mechanism leads to epoxidation and a high spin nonconcerted reaction is involved in the formation of the other products [121].

7.3.5 More Complex Transformations of Drugs

Almost all P450 oxidation reactions can be explained with the basic mechanisms presented here, utilizing the perferryl FeO^{3+} entity and possibly $\text{FeO}_2(\text{H})$, as already mentioned (Table 7.1). Some examples of seemingly more complex reactions have been presented elsewhere and are not recapitulated in this chapter [67,122], including ring expansion [104], ring contraction [123], and ring formation [124] (Fig. 7.11).

C–C and C–O bond coupling reactions are not unusual in P450 reactions involved in biosynthetic reactions in plants [126]. Such coupling reactions have now been observed with the (human) P450s 2D6 and 3A4 in the biosynthesis of mammalian alkaloids [127] (Fig. 7.12), and there are also some examples in drug transformations [128].

Figure 7.11 Some more “unusual” P450 reactions. (a,b) Ring expansions [104,125]. (c) Ring contraction [123]. (d) Ring formation [124].

Figure 7.12 C–C bond coupling catalyzed by the P450s 2D6 and 3A4 [127].

7.4 SUMMARY

While reading about the details of P450 mechanisms, one can get the impression that some of the work is esoteric and unlikely to be of practical use. What is true is that some elements of P450 catalysis will be more practical than others. Following are several points that a drug metabolism scientist should remember and will be of use.

1. The basic sequence of events in the catalytic cycle is shown in Fig. 7.2. One should remember that the scheme is not necessarily ordered as such [10] and that which events are rate limiting can vary considerably among the P450s and substrates.
2. The general concepts of abstraction by FeO^{3+} and oxygen rebound will explain most P450s, so mastering this basic chemistry is important.
3. Rearrangements are to be expected, either before the oxygen rebound or after product formation, so these possibilities should be remembered in considering how a product might be formed.
4. P450 regioselectivity is driven by thermodynamic and steric aspects of possible P450 reactions, which are not independent of each other. The chemical reactivity at a given site can be predicted, but even with the available P450 crystal structures, predictions are difficult. Predictions about regioselectivity—and particularly rates—are most feasible in a series of compounds where data already exist for some of the members.

ACKNOWLEDGMENTS

The work on P450 enzymes in the author's laboratory is supported in part by the National Institutes of Health R37 CA090426. The author thanks C. D. Sohl for comments on the manuscript and K. Trisler for assistance in preparation of the text.

8.1 INTRODUCTION

Our mechanistic understanding of the transcriptional regulation of cytochrome P450 (P450) expression has increased significantly in recent years, with the discovery and characterization of “orphan” nuclear receptors such as the constitutive androstane receptor (CAR) and the pregnane X receptor (PXR). The role of these receptors as mediators of the inductive effects of xenobiotics continues to be the subject of intensive investigation and has added a further layer of complexity to an already burgeoning area of research.

It has become clear that significant variability exists at almost every level of the processes that contribute to the ultimate functionality of P450 proteins, and transcriptional regulation is no exception. Expression of these proteins is controlled by transcription factors that not only vary in their expression level and the degree to which they bind and respond to different classes of ligands but are also themselves subject to alternative splicing, producing variant receptor forms with different spatiotemporal expression and functionality. It is clear that only by gaining a detailed understanding of these receptors will we have a greater appreciation of the intricacies of transcriptional regulation of P450s.

This chapter concentrates on those transcription factors involved in xenobiotic-induced expression, giving an overview of regulatory interactions and raising issues that have a bearing on transcriptional regulation, such as polymorphisms, splice variants, and species specificity. However, it is important to note that other transcription

factors that are not covered in this review - including the peroxisome proliferator activated receptors α and γ , the vitamin D receptor, and the oestrogen receptors α and β - are also involved in regulation of endogenous and basal cytochrome P450 expression.

8.2 TRANSCRIPTIONAL REGULATION OF CYTOCHROME P450s

8.2.1 Pregnane X Receptor (PXR)

The pregnane X receptor (PXR, also known as SXR, PAR, and NR1I2) is the most recently identified of the three main regulators of xenobiotic-induced CYP expression, with the mouse ortholog having been first identified by Kliewer *et al.* in 1998, closely followed by the identification of the human form by Blumberg *et al.* [1,2]. A ligand-activated orphan nuclear receptor was named the pregnane X receptor because of its activation by pregnenolone derivatives. Acting as a xenosensor, PXR is one of the key controllers of drug metabolism, in particular, for the expression of the CYP3A enzyme isoforms. In addition to the CYP3A enzymes, PXR, bound as a heterodimer to its partner, the retinoid X receptor (RXR), regulates a wide variety of P450s, as well as phase II enzymes and phase III drug transporters (Table 8.1). PXR is also promiscuous, being able to accommodate and be activated by a wide range of different ligands, both endogenous and exogenous (Table 8.2). This protein is expressed in many tissues, including those of heart, colon, stomach, and certain brain regions, although it is primarily expressed in the liver and small intestine [3]. Several splice variants have also been identified, which affect PXR-mediated transcriptional regulation (Section 8.3.3).

Flexibility in the ligand-binding domain (LBD) of PXR is the reason for its wide substrate specificity, with the binding pocket able to expand from its resting 1150 Å³ to more than 1600 Å³ when ligand bound. Large molecules, such as the macrolide antibiotic rifampicin (RIF), can therefore activate the receptor using an induced-fit

mechanism, which allows molecules to adopt various binding orientations before selecting the optimal configuration [23–25]. The LBD is predominantly hydrophobic in character, with Met243, Ser247, Gln285, Trp299, His407, and Phe420 commonly interacting with ligands [26,27]. Site-directed mutagenesis studies have indicated that even small changes in the LBD can have significant effects on the ligand-induced activation of PXR [25,26]. Interspecies variability in this region therefore has significant effects on the ligand activation profile (Section 8.3.2).

Nuclear translocation is a controlling factor in PXR-mediated P450 induction. However, because of difficulties with investigating translocation *in vitro*, namely, when PXR is overexpressed it spontaneously translocates to the nucleus [28], data regarding this mechanism remains limited. It has been reported that when inactive, PXR is bound in a complex with cytoplasmic CAR retention protein (CCRP) and HSP90, which retains the receptor in the cytoplasm [29,30]. Although the mechanism underlying PXR dissociation from the complex and translocation to the nucleus has not yet been elucidated, it is likely that a mechanism similar to that governing CAR dissociation from the retention complex is involved (Section 8.2.2). Once released from the cytoplasmic retention complex, PXR nuclear localization signals (NLSs) are targeted by importin- α proteins for nuclear import [29].

Upon entering the nucleus, PXR heterodimerizes with its binding partner, the RXR α , before binding to response elements in the promoter and enhancer regions of target genes (Fig. 8.1). PXR heterodimers preferentially bind direct repeat sequences possessing the half site AG(G/T)TCA separated by three nucleotides (DR3) and everted repeats of the half site separated by six nucleotides (ER6), that is, AG(G/T)TCAnnnAG(G/T)TCA and TGA(A/C)CTnnnnnnAG(G/T)TCA, respectively [15,16]. However, they are also able to bind other recognition sites, such as DR4, DR5, and ER8 motifs, although with lower affinity [31], thus accounting for the cross talk between receptors, which is an important contributor to P450 regulation.

A key component of transcriptional activation by nuclear receptors is the recruitment of coactivators and corepressors to promoter regions, following DNA binding. Coactivators of PXR, CAR, and AHR (aryl hydrocarbon receptor) are given in Table 8.3. As an example, PXR is a binding partner for the p160/SRC (steroid receptor coactivator) coactivator family, which recruits histone acetyltransferase complexes, such as cAMP response element binding protein/p300 (CREB), thus providing access to DNA strands for RNA-polymerase-catalyzed transcription [25]. These coactivators possess three LXXLL motifs that bind to the AF-2 helix, interacting with two charged residues on the receptor surface (Lys259 and Glu427) to form a charge clamp [24]. Crystal structures of SR12813 in complex with PXR and SRC-1 indicate that in the presence of coactivator, the ligand will bind in a single orientation. The combination of ligand and SRC-1 binding stabilizes the protein structure to restrict the flexibility of the LBD once an active ligand conformation has been achieved [25]. In contrast, corepressors are thought to bind in the absence of ligand, or in the presence of antagonists, retaining the AF-2 helix in a nonactive conformation [16]. Corepressors of PXR include the nuclear receptor corepressor (NCoR) and the silencing mediator of retinoid and thyroid hormone receptor (SMRT). SMRT possesses both ID1 and ID2 interacting domains, which consist of a CoRNR box (I/LXXI/VI) and the motif LXXXIXXXI/L, respectively [32]. PXR binds to the ID2 motif preferentially over the ID1, with the key interacting residues being Lys259, Gly270, and Pro423 of the PXR LBD and Arg2347, Lys2348, and Leu2350 of SMRT [32]. Site-directed mutagenesis studies show that mutation

of charged residues within the PXR LBD (Arg410Asn, Asp205Ala, Glu321Ala, and Arg413Ala) increases the binding affinity for corepressors, indicating a core role for these residues in the maintenance of basal PXR activation [32]. Acting in concert, the recruitment of coregulators therefore controls the expression of target genes, such as P450s, by regulating access of RNA polymerases to the promoter regions.

A further aspect of PXR-mediated regulation of P450s is posttranslational modification of PXR by phosphorylation. This modification is known to be critical to the correct function of other nuclear receptors, including CAR and AHR, but, until recently, had not been subjected to a systematic analysis with respect to PXR. Research from the Staudinger group has indicated that protein kinase A (PKA) interacts with PXR, but in a species-specific manner, synergizing with ligand activation in mice but repressing ligand-induced activation in rats and humans [37]. Protein kinase C (PKC) and CDK2 signaling has also been implicated. A recent mutagenesis study, in which 18 serine and threonine residues identified by either *in silico* site prediction or comparison with other receptors, has shed more light on the role of phosphorylation in PXR activity. These studies have shown that the phosphorylation state of certain key residues (Ser8, Thr57, Ser208, Ser305, Ser350, and Thr408) is involved in the control of heterodimerization, DNA binding, corepressor recruitment, and nuclear translocation [38]. The phosphorylation state of PXR therefore appears to be important in controlling gene expression. However, these observations require further studies to fully understand the role of phosphorylation in PXR function.

In summary, PXR is a key controller of P450 regulation, being associated with a wide variety of target genes. It also has an important role in many endogenous processes, including control of glucose homeostasis and the cholesterol and bile acid metabolism [15,16]. However, most importantly from a pharmaceutical perspective

is its role as the key regulator of the CYP3A enzymes, which are responsible for the metabolism of a significant proportion of currently used pharmaceuticals, and as a consequence involved in a significant number of drug–drug interactions [39]. As a key regulator of P450s, xenobiotics that interact with PXR could have a profound effect on their own metabolism as well as on the metabolism of other drugs given concomitantly. The promiscuity of PXR in terms of its ligand interactions and the wide range of genes it transactivates can result in severe drug–drug interactions [40–43]. As a consequence, PXR transactivation is investigated as a part of preclinical drug development programs. Regulation of this signaling pathway is still incompletely understood, although it is clear that it involves a complex interaction between coregulators, protein structure, and phosphorylation state.

8.2.2 Constitutive Androstane Receptor (CAR)

Initially identified in humans in 1994 as MB67 [44], and in the mouse in 1997 [45], the constitutive androstane receptor (CAR, NR1I3) is well established as a key regulator of P450 expression [16,39,46–57]. The genes targeted by CAR are numerous and varied, encompassing P450s (Table 8.1), phase II enzymes such as UDP-glucuronyltransferases, and phase III drug transporters, with CYP2B6 being prototypically induced (Cyp2b10 in mice, CYP2B1/2 in rat) [58,59]. Lacking a physiological ligand, this protein was also classed as an orphan nuclear receptor. However, as a nuclear receptor, CAR has some unusual properties, having both a different protein structure and displaying constitutive transcriptional activity [60].

As a consequence of the constitutive activity of CAR, molecules such as androstanol and androstenol have been referred to as *inverse agonists* because they actively repress constitutive CAR activity instead of antagonizing in the classical sense [61]. While not as promiscuous as PXR, CAR can be activated by numerous compounds (Table 8.2), but few operate by binding directly to CAR. Its constitutive basal activity means that it can transactivate genes without ligand binding, in response to externally acting signals that induce nuclear translocation [62]. This indirect activation pathway is a key mechanism in CAR-mediated transactivation, with phenobarbital (PB) induction of CYP2B being the classic example, and is suggested to be the major activation pathway for this molecule [63,64]. These phenomena are dependent on several key structural features of CAR and the increasingly understood mechanism of nuclear translocation, which are considered below.

Structurally, a protein consists of three domains: (i) a highly conserved N-terminal DNA-binding domain, (ii) a hinge region, and (iii) a variable C-terminal domain associated with ligand binding (AF-2 domain), dimerization with the CAR-binding partner (RXR α), and transcriptional activation [54]. The ligand-binding pocket (LBP) is significantly smaller than that of PXR at approximately 675 Å³ in humans and is predominantly hydrophobic in nature. The conformation of the AF-2 domain within the LBP is thought to be vital to the constitutive activity of the protein, although it is not accessible for ligand binding, being protected by the side chains of Phe161 (also key in constitutive activity), Asn165, Phe234, and Tyr326, which are conserved across all mammalian orthologs of CAR [65,66]. It has also been suggested that disruption of the AF-2 conformation is responsible for switching CAR to its inactive form, such as is seen upon inverse agonist interaction [27].

Although CAR is described as constitutively active, it is unable to activate transcription of downstream genes in the absence of an external signal because of regulatory mechanisms controlling its translocation to the nucleus. In the absence of ligand or indirect activation, CAR is sequestered in the cytoplasm, bound to a complex consisting of CCRP and HSP90, along with other accessory proteins [67,68]. In response to direct or indirect ligand challenge, NLSs are activated, resulting in dissociation from this complex. Once the ligand is activated and released from the cytoplasmic retention complex, active CAR is translocated into the nucleus via an importin/Ran-GTP mediated process involving NLS binding to IPO13 [69].

The molecular trigger for, and underlying mechanism of, nuclear translocation is still unclear, although recent research has implied an essential role for cellular signaling pathways and phosphorylation status, especially in indirect control [28]. Although the role of phosphorylation state in CAR translocational control had been described previously, it was not until 2009 that the Thr38 amino acid was identified as the key residue in regulation of human constitutive androstane receptor (hCAR) translocation. Phosphorylation of Thr38 by PKC inactivates CAR by destabilizing the helix containing the C-terminal region of the first zinc finger, resulting in ablation of DNA binding [70]. However, on Thr38 dephosphorylation, the disrupted helix regains its stability, resulting in nuclear translocation and transactivation of downstream genes. It has been suggested that an essential process in PB-induced activation is the recruitment of protein phosphatase 2A (PP2A) to the retention protein complex in mouse hepatocytes, subsequently inducing translocation [71,72]. PP2A has therefore been suggested as a candidate for the dephosphorylation of this residue, acting in concert with other cofactors recruited to the CCRP/HSP90 complex. In addition, a recent report by Koike *et al.* identifies extracellular signal-regulated kinase (ERK) 1/2 as the endogenous signal controlling sequestration of CAR in the cytoplasm, with dephosphorylation of ERK 1/2 being sufficient to induce nuclear translocation [73]. AMP-activated protein kinase has also been suggested to influence CAR localization following PB treatment, although currently available data is conflicting [64,74–77]. Mutoh *et al.* suggest a model for both direct and indirect activators, in which PKC phosphorylates and PP2A dephosphorylates Thr38 to control nuclear translocation. The signal controlling the phosphorylation state of this residue appears to be extracellular signal-regulated kinase (ERK) 1/2 [70,73]. However, a membrane-bound regulatory subunit of protein phosphatase 1b, PPP1R16A, has recently been shown to interact with CAR, inducing translocation, which agrees with a report which localizes CAR at the cell surface in addition to the cytoplasm [78,79]. This suggests another layer of complexity in controlling nuclear translocation.

Once in the nucleus, CAR binds to RXR α in a head to tail arrangement and the resulting heterodimer binds to response elements in the promoter of target genes (Fig. 8.1). CAR will preferentially bind to three binding motifs: (i) DR4 (e.g., AGTTCAnnnnnAGTTCA), (ii) DR5 (e.g., AGTTCAnnnnnAGTTCA), and (iii) ER8 (e.g., TGAACtnnnnnnnnAGTTCA). However, CAR can bind other motifs, such as ER5–ER10 types, but with lower affinity [15,80]. Unusually, CAR is also able to bind to DNA as a monomer, having a preference for DR4 motifs [80]. The optimal binding site for monomeric CAR was found to be AGAGTTCA. Binding to these motifs as a monomer is as strong as that of the T₃ thyroid hormone receptor, and the preference for monomeric binding is more marked in humans than in mice. However, if the 5' nucleotide flanking sequences contain pyrimidine nucleotides, the binding

tendency of monomeric CAR is greatly reduced. All these binding motifs have been identified in the phenobarbital response element (PBREM) commonly found in CAR target genes [80]. Once bound, activated CAR will recruit coactivators/corepressors to modulate gene expression (Table 8.3).

Although this chapter has concentrated on the role(s) of CAR in xenobiotic metabolism, it is important to remember that CAR also has many endogenous functions. It is particularly important in control of lipid metabolism and energy homeostasis, appearing to act as an energy sensor, and influencing metabolism accordingly [17,81–86]. CAR is also involved in the control of bilirubin metabolism and heme biosynthesis, as well as bile acid and steroid/thyroid hormone homeostasis. For a recent review of this area, see di Masi *et al.* [15]. The range of endogenous roles with which CAR is involved means it is vital to consider the potential for functional cross talk between endogenous control and xenobiotic metabolism. For instance, the energy state of an organism can have significant effects on the uptake and pharmacokinetics of a drug because nutritional state can influence the induction of P450s by CAR [17]. Other considerations relating to CAR-induced xenobiotic metabolism include differential regulation due to species specificity, gender-specific induction, and the circadian control. Species specificity is discussed in more detail later in this chapter. Circadian control is a potentially important determinant of CAR expression and induction. CAR exhibits a circadian expression profile in mice because of its regulation by the PAR-domain basic leucine zipper transcription factors DBP (albumin D-box binding protein), TEF (thyrotroph embryonic factor), and HLF (hepatic leukemia factor), all of which are regulated by core components of the circadian machinery [87]. This results in a temporal induction of CAR target genes. Since downstream genes, such as P450s, are likely to display circadian expression profiles as a result, it is understandable that the clinical profile of certain drugs, such as cyclophosphamide and mitoxantrone, improves when dosing time in terms of circadian cycle is considered [87]. This feature should always be considered when investigating compounds that are likely CAR interactors, particularly in mouse models.

Overall, CAR regulation of P450 expression is complex, involving structural activation, regulation by signaling pathways, and interaction with various factors influenced downstream by CAR, including energy metabolism. It is, therefore, important when investigating compounds that appear to induce P450s via a CAR-dependent mechanism to consider that the endogenous control of CAR and the way in which it influences other homeostatic mechanisms, such as energy homeostasis, can have a significant effect on P450 expression profile and thus xenobiotic metabolism.

8.2.3 Aryl Hydrocarbon Receptor

The AHR has been known significantly longer than PXR and CAR, having been first identified in 1976 as the cytosolic receptor mediating 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)-dependent induction of aryl hydrocarbon hydroxylase activity [88]. However, unlike PXR and CAR, the AHR is not a nuclear receptor but is the only known ligand-activated member of the basic helix-loop-helix (bHLH)/period (PER)-aryl hydrocarbon receptor nuclear translocator (ARNT)-single minded (Sim) (bHLH-PAS) family of transcription factors. AHR ligands can be classified as synthetic, for example, dioxins and halogenated polycyclic aromatic hydrocarbons, and naturally occurring, such as flavonoids, indoles, and arachidonic acid metabolites [6,22,89]. As

a family, these proteins are implicated in the regulation of physiological processes, including organ development, metabolism, and stress and immune response [90]. However, one of the key roles of AHR is the control of xenobiotic metabolism.

AHR is responsible for the transactivational control of a variety of P450s (Table 8.1), most notably CYP1A1, CYP1A2, and CYP1B1, with CYP1A1 being considered a model enzyme for studying AHR-mediated gene activation. In order to modulate transcription, AHR heterodimerizes with its binding partner ARNT [33]. The transcriptional activation domains (TADs) of both molecules, once activated by ligands, activate transcription by inducing DNA binding via a subdomain N-terminal to the HLH domain. Both AHR and ARNT possess one TAD in the C-terminal region, with both containing glutamine and hydrophobic residues. However, the TAD of AHR also has acidic characteristics, whereas that of ARNT is rich in serine, threonine, and proline [91]. It is worth noting that while the N-terminal domain of AHR is well conserved across species, the C-terminal domain, and thus the TAD, is significantly divergent (58% identity between human and mouse forms) [92–94]. As a consequence, there are significant species differences in response to ligands (see Section 8.3.2 for details). Following activation, the AHR/ARNT heterodimer binds to the xenobiotic response element (XRE) in the promoter and/or enhancer regions of target genes (Fig. 8.1). Unlike classical bHLH proteins, the AHR/ARNT heterodimer binds to an asymmetric recognition site, binding to the core sequence of the XRE—*TNGCGTG* [92,95,96]. It has also been suggested that nucleotides adjacent to, but not part of, the core binding sequence are important for regulation of some genes [95]. Following DNA binding, AHR/ARNT recruits coactivators (Table 8.3) and other proteins, such as Mediator D and TFIID, resulting in chromatin remodeling and recruitment of RNA polymerases and in the initiation of gene expression (for a review of DNA binding, see Ref. 95).

Nuclear translocation is also a key step in the control of AHR-induced transcriptional regulation. AHR protein, which is inherently unstable in the absence of ligand, is stabilized in the cytoplasm by a complex consisting of two molecules of HSP90 and one each of hepatitis B virus X-associated protein 2 (XAP2) and the co-chaperone p23 [97–99]. The E3 ubiquitin ligases, C-terminal of HSP70 interacting protein (CHIP), and Cullin 4B also bind to AHR, which could explain the rapid degradation of free, monomeric AHR within cells [97]. In response to a molecular trigger, AHR dissociates from the core complex and localizes to the nucleus where it heterodimerizes with its binding partner to activate gene expression. At present, the signals regulating nuclear translocation are still being elucidated; however, there appears to be at least two separate mechanisms depending on whether the receptor is activated by ligand or an endogenous signal.

HSP90 has an important role in maintaining AHR stability and structure, with the central region binding to both the bHLH and PAS domains of AHR. HSP90 appears to be essential for maintaining AHR in its ligand-binding conformation, with AHR losing its dioxin-induced activity when HSP90 is disrupted *in vitro* [100–102]. Ligand binding appears to disrupt the binding of HSP90 to the PAS domain, which is adjacent to or just within the LBD, but not to the bHLH region, resulting in a conformational change that retains HSP90 binding during nuclear translocation. To explain this phenomenon, McGuire *et al.* [101] postulate that after ligand binding, HSP90 promotes a conformational change to accommodate the binding by AHR's dimerization partner, ARNT, following translocation to the nucleus, and therefore remains bound to AHR through the bHLH domain during nuclear shuttling. XAP2 is a 38-kDa protein with

significant homology to the immunophilins, such as FKBP52 [99]. Although not absolutely required for the structural integrity of the cytoplasmic core complex, XAP2 does appear to have a significant role in maintaining cytoplasmic localization [103]. In mice, nuclear localization appears to rely on importin β , which recognizes the bipartite NLS found in AHR. In the cytoplasm, XAP2 binding in the core complex masks the NLS, preventing importin binding and subsequent nuclear localization [103]. Ligand binding induces a conformational change in XAP2, resulting in dissociation of XAP2 and HSP90 from AHR. This unmaskes the bipartite NLS, making it available for importin binding and thus nuclear import [98,104]. However, XAP2 does not seem to fulfill the same role in humans, as it appears to shuttle into the nucleus still bound to AHR [105,106]. This mechanism also involves PKC-mediated phosphorylation of two serine residues adjacent to the NLS—Ser12 and Ser36—which inhibits nuclear translocation by masking the NLS from importins [107].

Although ligand-dependent nuclear translocation seems to rely on ligand-induced conformational change of XAP2 and HSP90, evidence for another pathway involving cyclic-nucleotide-dependent signaling has been reported [97,98,108,109]. cAMP has been shown to interact with the AHR core complex and induce nuclear translocation [109]. However, the conformational change induced by this interaction reduced the ability of AHR to dimerize with ARNT, changed the DNA recognition sequence of AHR, and reduced dioxin-induced target expression [98,109].

Following nuclear translocation, it has been reported that phosphorylation of AHR and ARNT is essential for heterodimerization and thus DNA-binding activity [22]. The kinases involved were PKC and members of the ERK/MEK signaling pathway. This once again illustrates the importance of cooperative control with endogenous signaling pathways in xenobiotic metabolism. A novel nuclear binding partner has also been identified, which acts through the cAMP-related signaling pathway: the RelB subunit of NF- κ B [110–112]. This heterodimer behaves in a PKA phosphorylation-dependent manner, with AHR DNA binding identified in the promoter region of interleukin-8. Although this alternative binding partner has a role in coregulation of inflammatory genes, acting in concert with the NF- κ B pathway, any possible role in P450 regulation has yet to be investigated.

In summary, AHR is a promiscuous receptor that has a key role in metabolic response to environmental and dietary toxins. The mechanisms regulating AHR-induced P450 regulation are complex, requiring cross talk between many signaling and physiological processes. It is worthy to note that the majority of AHR research to date has been conducted *in vitro*, especially using murine cell lines. This has a number of limitations, including, in particular, AHR function is linked with a number of physiological processes, therefore important interactions will be missed and there are significant species differences in the structure and function of AHR. The application of AHR-humanized mice could be of use to further establish the *in vivo* regulation of this signaling pathway [113].

8.2.4 Receptor Cross Talk

In order to maintain a robust response to chemical challenge, multiple transcription factors have evolved to modulate P450 expression. This has created a complex interacting network of gene regulation [114]. The cross talk between the transcription factors, both in the ligands with which they interact and the downstream genes that they regulate,

allows the systems to be fine-tuned for the detoxification of specific compounds and the interactions between endogenous and exogenous pathways to be controlled. It is, therefore, imperative to understand the degree to which this phenomenon controls both *in vitro* and *in vivo* drug-metabolizing enzymes. This section discusses the cross talk between the three main transcription factors and the regulation of certain key P450s involved in drug metabolism.

8.2.4.1 CYP1A1/2. The CYP1A enzymes are associated with the metabolism of environmental toxins and aromatic hydrocarbons, providing protection against acute dioxin-induced hepatocellular necrosis and hepatic inflammation [4,5,115,116]. They are primarily under the control of AHR, with *Cyp1a1* and *Cyp1a2* possessing conserved XRE clusters in their proximal promoters [116]. However, other response elements have been located in the promoters of these genes, suggesting regulatory roles for other transcription factors. Also, PXR ligands can induce AHR target genes through the transcriptional regulation of AHR [4]. Yoshinari *et al.* [5] recently provided evidence that binding of the hCAR/RXR α heterodimer to a conserved ER8 motif within the proximal promoter of the CYP1A1 and CYP1A2 genes increases their expression. This finding suggests that drugs that activate CAR could alter the metabolism of CYP1A1 and CYP1A2 substrates and therefore be a source of drug–drug interactions. Glucocorticoid response elements (GREs) have also been identified in the promoter region of the rat *CYP1A1* gene, which, once activated, interact with the initiation complex to enhance AHR-induced transcription [54]. However, regulation by this mechanism appears to be species specific and does not occur in humans.

Inflammation has been reported to negatively regulate CYP1A1 expression, with exposure to UV-B repressing the induction of CYP1A1 immediately following irradiation, although CYP1A1 is induced in an AHR-dependent manner several hours following irradiation [115,117]. This was attributed to direct interaction between AHR and the NF κ B RelA (p65) subunit, interfering with cofactor recruitment to the promoter. The repression of *Cyp1a1* expression in response to oxidative stress had been reported by Morel and Barouki, who identified nuclear factor 1 (NF1) as the mediator of this effect [118]. Reciprocal cross talk between AHR and Nrf2 has also been recently reported, with XRE sequences being located in the Nrf2 promoter [12], and ARE sequences in the AHR promoter [119]. It has been suggested that a functional protein interaction may also exist between these molecules, although no data is currently available [120]. The reciprocal cross talk between these two systems further highlights the key role of AHR in the protection of the body from damage caused by electrophilic metabolites.

Regulation of CYP1A expression is therefore controlled by a number of core interacting transcription factors. However, because of the many endogenous roles played by the AHR, they are also subject to regulatory control by diverse signaling pathways, including those involved with inflammation and oxidative stress response, playing a key role in protecting the body from xenobiotic challenge.

8.2.4.2 CYP2B6. CYP2B6 metabolizes a wide range of drugs, including cyclophosphamide, valproic acid, ketamine, aminopyrine, methadone, and bupropion [59]. Its overall role in drug metabolism in man, however, has been considered minor [59,121]. CYP2B6 is induced by activators of hCAR, with the activated hCAR/RXR α heterodimer binding to the DR4 motif in the phenobarbital-responsive-element module

(PBREM) in the promoter [54,59]. However, cross talk with human pregnane X receptor (hPXR) has also been implicated in CYP2B6 regulation, through binding to the DR4 motif, all be it with lower affinity. A response element termed the *distal xenobiotic responsive enhancer module* (XREM) has also been identified as activated by either hCAR/RXR α or hPXR/RXR α [122]. This element works synergistically with the activated PBREM [59,122].

Although cross talk with PXR is reported to be part of the mechanism in the control of CYP2B6, other receptors are also implicated. For instance, in rodents, the glucocorticoid receptor (GR) directly activates CYP2B/Cyp2b expression [123,124]. Although the GR does not directly activate CYP2B6 in humans, it can affect CYP2B6 expression indirectly through induction of CAR and PXR [59]. Recent studies from the Negishi group have suggested that for maximal activity, the CYP2B6 promoter can be synergistically activated by the PBREM and a novel 52-bp response element, known as the *okadaic acid response element* (OARE_{KI}) (Fig. 8.2) [125]. The OARE_{KI} contains a DR1 motif, which possesses an HNF4 α binding site, a CACCC motif, which binds early growth response 1 (EGR1) protein, and an E box motif. EGR1 binding is required for maximal CAR-induced CYP2B6 activity, facilitating CAR/HNF4 α cross talk by inducing DNA looping to bring the proximal OARE_{KI} into proximity with the distal PBREM [126]. A recent study has demonstrated that the CCAAT/enhancer binding protein α (C/EBP α) and HNF4 α cooperate with CAR to control CYP2B6 expression [121]. HNF4 α binding to a proximal element located in the OARE_{KI} (–217 bp) favors

Figure 8.2 Regulatory network controlling CYP2B6 expression. *Source:* Adapted from Benet *et al.* [121], with additional information from Inoue and Negishi [126] and Wang and Tompkins [59]. (See color insert.)

CAR interaction, whereas binding to the distal region (–1642 bp) favors interaction with C/EBP α (Fig. 8.2). Variation in expression and binding of HNF4 α and C/EBP α to the CYP2B6 promoter has been correlated to interindividual variations in CYP2B6 expression and activity, suggesting their importance in the regulation of this gene [121]. It is clear that CAR-induced transcriptional regulation of CYP2B6 involves intricate cross talk between CAR, HNF4 α , EGR1, and C/EBP α as a minimum. However, the role of PXR in this mechanism remains to be clarified.

8.2.4.3 CYP2C8. CYP2C8 is the most inducible gene in the CYP2C family, with a role in the metabolism of drugs such as rosiglitazone, paclitaxel, cerivastatin, and chloroquine, in addition to endogenous compounds, such as arachidonic acid [9]. The regulation of this protein remains poorly characterized, although DR4 binding at –8.8 kb is needed for CAR and PXR-mediated CYP2C8 induction [9]. Both CAR and PXR can bind to this element in response to ligands. However, Ferguson *et al.* [9] found that this response is not apparent when the reporter gene assay is performed in the HepG2 cell line but is seen when using metabolically competent primary human hepatocytes, demonstrating the limitations of HepG2 cells for drug induction studies. As with CYP2B6, basal expression of CYP2C8 involves HNF4 α binding to a DR1 motif in the basal promoter region. A second functional HNF4 α binding site has also been identified in the proximal promoter region [127]. Site-directed mutagenesis of the CYP2C8 promoter has shown that both HNF4 α sites are important for RIF-induced PXR-mediated expression of CYP2C8, with that in the proximal promoter region being essential. Also, silencing of HNF4 α using RNA interference (RNAi) decreased basal CYP2C8 reporter activity by 48% and abolished RIF-mediated induction. However, this treatment also repressed expression of CAR and PXR by 60% and 40%, respectively [127]. In light of the current limited information, further studies on the role of CAR in CYP2C8 control are required.

In addition to the above regulatory pathways, the GR also appears to be involved in the induction of members of the CYP2C gene family, with a functional GRE being located in the proximal promoter region in many CYP2C genes [9,54]. Ferguson *et al.* [9] demonstrated that CYP2C8 induction by the prototypical GR activator, dexamethasone, occurs by direct interaction with the GRE located in the promoter region of the gene, and not by interaction with PXR or CAR. A recent study in HepG2 cells identified retinoic-acid-receptor-related orphan receptor (ROR) response elements (ROREs) in the promoter of CYP2C8, which are activated by ROR α 1, ROR α 4, and ROR γ 1 isoforms [128]. The importance of RORs in the control of CYP2C8 was further supported by the finding that knockdown of the three isoforms resulted in a 50% decrease in CYP2C8 mRNA. Since natural agonists of these receptors include cholesterol and its metabolites, CYP2C8 expression is likely to be influenced by normal physiological processes. These receptors are also linked to the control of circadian rhythm and therefore could be associated with circadian expression of the CYP2C genes. In summary, the regulatory control of CYP2C8 is still poorly understood, although certain key factors have been identified. More research is therefore required to integrate these signals into an understandable network and to more fully characterize regulation by CAR and PXR.

8.2.4.4 CYP2C9. CYP2C9 is the most highly expressed of the CYP2C family [129], with identified substrates including tolbutamide, diclofenac, and *S*-warfarin [130]. In

human hepatocytes, CYP2C9 could be regulated with prototypical PXR, CAR, and GR activators (RIF, PB, and dexamethasone, respectively), indicating that all three receptors have a role in the regulation of this enzyme [131]. Subsequent studies suggested that CAR plays a role in the basal expression of CYP2C9, with constitutive expression in HepG2 cells increasing with stable transfection of mouse or hCAR [131,132]. Two DR5 response elements, in a configuration similar to that of the PBREM and XREM modules, are located in the proximal promoter at -2899 bp and preferentially bind CAR over PXR [132]. A DR4 CAR/PXR binding motif at -1839 bp has also been identified [131]. Mutagenesis of these binding sites provided evidence that both are sensitive to CAR activation [132]. The induction of CYP2C9 by treatment with RIF, hyperforin, and PB has been shown to be mediated by hPXR binding to the DR4 response element [10,133]. The proximal DR4 binding site is therefore essential for activation, with the distal site acting in a cooperative capacity.

HNF4 α plays an essential central role in the regulation of CYP2C9, with HNF4 α binding sites located at -211, -185, and -152 bp. The site at -185 bp plays a central role in HNF4 α -induced CYP2C9 expression and CAR/PXR synergism [127,134]. The HNF4 α binding sites cooperate with the CAR/PXR responsive DR4 motif for maximal gene expression [127]. The underlying mechanism appears to be as a result of recruitment of a number of coactivators to the promoter, including cAMP response element binding protein (CBP), PGC-1 α , PRIP-interacting protein with interacting methyltransferase (PIMT) domain, and nuclear receptor coactivator 6 (NCOA6) [135]. Current evidence suggests that NCOA6 forms a bridge between CAR and HNF4 α bound to their respective response elements by direct interaction with the LXXLL motifs of each. NCOA6 therefore acts as a mediator promoting synergistic cross talk between CAR and HNF4 α . It is not yet clear whether the same mechanism applies to hPXR-mediated control.

Other pathways that do not appear to directly interact with CAR/PXR-induced CYP2C9 expression have also been detailed. An imperfect GRE sequence at -1675 bp allows direct activation of the promoter by the GR, which appears to act synergistically with CAR/PXR [132]. HNF3 γ , also known as FOXA3, has been implicated in the regulation of CYP2C genes, being found to bind to HNF3 γ response elements in the promoter region, although a mechanism has yet to be elucidated [136]. A study by Drocourt *et al.* [137] suggested that the VDR can also regulate CYP2C9 expression. However, they point out that the concentrations of 1 α ,25-dihydroxyvitamin D₃ required for this interaction are above the levels seen physiologically, and therefore, the relevance of this interaction is questionable. A recent study has also shown the transcription factors GATA-2, -4, and -6 induce CYP2C9 through direct interaction with response elements in the promoter [138]. Again, any potential cross talk with other motifs has yet to be investigated, but the tissue-specific nature of GATA transcription factors could make this an interesting pathway when considering gene expression in extrahepatic tissues.

The regulation of CYP2C9 appears unusual in comparison to the other commonly inducible P450s. Although, HNF4 α is again central to promoter activation, regulation by CAR and PXR is such that constitutive expression appears to be mediated through a CAR-mediated pathway, whereas ligand induction occurs through a PXR-mediated pathway, showing a more physiologically cooperative cross talk between these receptors than is often seen. Cross talk mediated through cofactors is also apparent in the mechanism underlying cooperation of CAR and HNF4 α through mediation by NCOA6.

8.2.4.5 CYP3A4. CYP3A4 is the major P450 expressed in human liver and is responsible for the metabolism of approximately 60% of current drugs. The variation in CYP3A4 expression due to enzyme induction is therefore a major determinant of drug–drug interactions [39]. The key regulator of CYP3A4 expression is PXR, with the hPXR/RXR α heterodimer binding to an ER6 PXRE motif located at –172 bp relative to the transcription start site in the proximal promoter region [139–141]. Mutation of this element led to a 50% reduction in RIF-mediated response, indicating that this motif acts cooperatively with other regulatory elements [140]. A distal XREM enhancer has been identified at approximately –7800 bp, consisting of three nuclear-receptor-binding sites, dNR1-3. Disruption of the PXRE in the proximal promoter and the dNR1 imperfect DR3 binding motif in the distal XREM represses xenobiotic response by approximately 85%, indicating that both elements are essential for CYP3A4 expression. The dNR3 site is also required for maximal gene expression [140]. A further polymorphic enhancer module, known as the *constitutive liver enhancer module of CYP3A4* (CLEM4), has been identified at –11.4 kbp [142]. This is also required for maximal gene expression. This module contains multiple cis-acting elements, including binding sites for HNF-1, USF-1, AP-1, and HNF4 α , as well as a perfect ER6 PXR binding motif. This enhancer region acts synergistically with the distal XREM and proximal promoter in PXR-mediated *CYP3A4* induction [143]. This region also appears to be involved in constitutive CYP3A4 expression [142]. However, the motif located in this region has been found to be significantly less competitive for PXR/RXR α binding relative to motifs found in the distal XREM and proximal promoter, instead the motif has a higher affinity for a PXR homodimer *in vitro* [143]. This homodimer has yet to be described *in vivo*, but potentially, this could result in a previously uncharted regulatory mechanism associated with CYP3A4 control.

All PXR binding motifs described above have also been shown to bind hCAR, although binding to the proximal promoter region alone is insufficient for CAR-induced expression. Therefore, evidence suggests that CYP3A4 is coordinately regulated by hCAR and hPXR [144,145]. Although PXR/CAR cooperation appears to be the main regulatory pathway connected to ligand-induced control of CYP3A4, neither are essential for constitutive expression, with individual disruption of these genes *in vivo* having no influence on basal CYP3A4 expression [142]. Istrate *et al.* [146] have used gel shift and LS174T-based reporter gene assays to show that a number of transcription factors can bind the ER6 and DR3 motifs, thus decreasing PXR-mediated gene induction through competition. For instance, the thyroid receptor (TR) α 1 can bind to the response elements to repress CYP3A4 basal and ligand-induced expression. The ratio of PXR:TR α 1 was moreover found to be correlated to basal expression level, suggesting a role in endogenous control. The VDR has also been found to compete with PXR for ER6, DR3, and DR4 binding sites to induce CYP3A4 expression in rat and human liver and intestinal slices, all with lower activity than PXR [137,147]. However, a recent study has shown that VDR and PXR can act synergistically in intestinal cell lines, apparently through VDR binding to the PXRE located in CLEM4 [148].

HNF4 α also has a significant role in controlling CYP3A4 expression. Tirona *et al.* have identified a DR1, HNF4 α binding site immediately upstream of the dNR1 and dNR2 binding sites in the XREM (–7783 bp). This was shown to be essential for ligand-induced promoter activity. *In vitro* reporter transactivation assays in HepG2, Caco-2 and HeLa cell lines indicated that basal and induced promoter activities are mediated through PXR/CAR, with the activity increasing synergistically in the presence of

HNF4 α [149]. In contrast, the PXRE located in CLEM4 is flanked by two downstream HNF4 α binding motifs [143], which suppress rather than facilitate PXR/CAR-induced gene expression as a consequence of HNF4 α interference with PXR DNA binding. Liu *et al.* also reported that while disruption of the ER6 motif in the CLEM4 domain has no effect on basal expression, disruption of the DR3 motif in the XREM results in a decrease in basal activity. Other regulators of CYP3A4 expression have also been suggested. These include STAT1, HNF1, HNF3 β (FOXA2), HNF3 γ (FOXA3), and C/EBP α [150]. A systematic *in vitro* analysis in HepG2 and HuH7 cell lines has been performed by Bombail *et al.*, in which putative binding sites were disrupted to identify functional interactions [151]. This study identified C/EBP α as a regulator of CYP3A4 expression, with mutation of the C/EBP α binding site at -132 bp causing a 60% decrease in basal expression and a decrease in $I_{\max}$ associated with RIF-, PB-, and metyrapone-mediated activation. In a previous work, two distal C/EBP α sites (located at -1402 and -1668 bp) were identified in the activation of CYP3A4 expression. HNF3 γ is also a putative regulator, with a binding site located at -1730 bp. However, this receptor does not activate CYP3A4, but rather synergizes with C/EBP α , promoting gene expression by chromatin remodeling [151,152]. In addition to these findings, Bombail *et al.* reported that disruption of a putative Sp1 site at -104 to -97 bp resulted in a 50% decrease in promoter activity following PB treatment. Despite the presence of a putative GRE in the proximal promoter region, it is likely that GR agonists influence CYP3A4 expression by inducing PXR expression rather than interacting directly with the promoter [147,153]. CYP3A4 expression is also influenced by various physiological processes, as demonstrated by its regulation by FOXA2 and FOXA3, which have numerous endogenous roles, including embryonic development, organogenesis, and glucose homeostasis [154]. Other endogenous modulators include the HIF-1 α transcription factor, which is upregulated in response to oxidative stress, and interacts to downregulate drug-metabolizing enzymes, including CYP3A4, in order to prevent the production of reactive oxygen species [155]. This seems to act through an indirect mechanism, such as downregulation of PXR and CAR, rather than through direct promoter binding. It is also important to remember that these transcription factors are subject to control by endogenous signaling molecules. This is highlighted by a recent report linking CYP3A4 expression to the cell cycle via phosphorylation of PXR by cyclin-dependent kinase 2 [156].

As this section has shown, although each of the enzymes discussed is preferentially controlled by a given transcription factor or nuclear receptor, a large variety of signaling pathways and coregulating molecules interact to control gene expression. The redundancy inherent in this system could be explained by the need to adapt to a wide range of environmental demands and endogenous stimuli. Our understanding of the interactions underlying transcriptional control is rapidly increasing. However, the networks we have currently identified are simplistic, omitting key endogenous signaling information that can have dramatic consequences for drug metabolism. While this section has aimed to give a broad overview of interaction at the level of P450 promoter regulation, it has of necessity excluded another level of functional cross talk, which exists between different nuclear receptors and transcription factors. Several reviews are now available, which discuss functional cross talk between nuclear receptors and certain transcription factors [15,16,114]. This interaction can significantly affect downstream regulation of target genes and thus the overall P450 expression profile.

8.3 OTHER CONSIDERATIONS FOR TRANSCRIPTIONAL REGULATION OF CYTOCHROME P450s

8.3.1 Methodological Challenges

Understanding P450 regulation is a vital step toward understanding drug interactions. Although the mechanisms underlying P450 transcriptional regulation are becoming clearer, methodological difficulties have introduced other issues that must be considered when analyzing current evidence.

Although *in vitro* methods, such as reporter gene assays, have been used to identify P450-inducing agents and mechanisms of transcriptional control, cell-based systems are unable to fully model transcriptional activation. Traditional overexpression systems have limitations because PXR and CAR will spontaneously translocate to the nucleus, probably because the members of the cytoplasmic retention complex become saturated [28,157]. This removes one of the key mechanisms underlying transcriptional regulation. A further problem is that with the exception of primary hepatocytes and a handful of immortalized cell lines, such as the HepaRG model [158–160], the majority of cell lines do not express physiologically relevant levels of both the P450-related transcription factors or P450s themselves. Cells also have the disadvantage that they cannot model systemic interactions, a significant problem when transcriptional regulators are influenced by systemic cues, such as hormonal signaling and energy state.

The use of conventional animal models to study ligand induction of P450s is therefore common, being able to model induction in a more physiologically relevant manner. However, because of the divergence of the metabolic system between species, models do not accurately predict P450 induction in humans [161]. The consequences of this can be profound. For instance, from a pharmaceutical perspective, failing to consider potential differences in drug metabolism could result in drugs reaching clinical trials that are therapeutically ineffective or, much more importantly, toxic to humans [162]. Species specificity is therefore a major issue to be addressed when considering results from animal models.

8.3.2 Species Specificity

The mechanisms underlying species specificity in drug induction are complex. However, species differences in P450 induction can often be ascribed to differences in the amino acid sequence of the LBD of the transcription factor involved [7,163–168]. Changes in the activity of NLS sequences have also been associated with alterations in nuclear localization, resulting in aberrant gene transcription [92,105,106,169,170]. Lichti-Kaiser *et al.* [37] have also identified species specificity in the response of hPXR and mPXR (mouse pregnane X receptor) to the cAMP nucleotide signaling pathway. CYP3A4 expression was found to be synergistically increased on treatment with RIF and the PKA inhibitor H89, whereas it decreased following treatment with H89 and pregnenolone-16 α -carbonitrile (PCN). However, the study compared data from HepG2 cells transduced with an adenoviral expression vector containing hPXR with that from primary mouse hepatocytes, which may influence the findings. In the case of AHR, species-specific differences in receptor protein stability (hAHR < mAHR) and histone deacetylase complex recruitment have been implicated in differential response [170]. Improved understanding of species differences in nucleocytoplasmic shuttling,

TABLE 8.4 Examples of Species-Specific Ligands for PXR and CAR

Drug	Interacts with	Species			
		Mouse EC ₅₀ (nM)	Action	Human EC ₅₀ (nM)	Action
PCN	PXR	200–700	+	>10,000	N/A
Rifampicin		Weak		200–3000	+
SR12813		4100	+	120–200	+
Hyperforin		NR		23	+
5 β -Cholestan-3 α ,7 α , 12 α -triol		2500	+	5000	+
TCPOBOP	CAR	20–100	+	Weak	N/A
CITCO		Weak		25–304	+
5 α -Androstan-3 α -ol		250–1500	–	1000–>10,000	–
Meclizine		25	+	500–1000	–
5 β -Pregnane-3,20-dione		670–3000	+	>10,000	Weak+
				$\gg$ 10,000	–
2,3,7,8-Tetrachlorodibenzo- <i>p</i> -dioxin	AHR	0.6	+	0.4–9	+

Includes EC₅₀ (nM) where data is available.

NR, not reported; +, agonist; –, antagonist (inverse agonist, CAR only).

PXR and CAR data adapted from Refs 15 and 16. AHR data adapted from [177] (mouse), [178] (human), and [179].

cell signaling pathways and subsequent activation mechanisms is therefore of central importance. The availability of mouse models humanized for both the receptors which mediate drug induction as well as the P450's involved can help circumvent many of these problems.

Although the precise mechanisms have yet to be fully elucidated, numerous P450 inducers have been identified which interact with transcription factors in a species-dependent manner. A selection of these ligands has been detailed in Table 8.4. These include numerous drugs, endogenous compounds, environmental contaminants and certain herbal medicines. Most of this data has been generated using *in vitro* reporter gene assays, which are a useful model for identifying species-dependent ligand effects on transactivation activity of transcription factors. However, there are certain ligands that have proved of particular importance in the study of receptor activation. The macrolide antibiotic RIF and PCN have been shown to be species-specific activators of PXR, with RIF activating hPXR and PCN activating mPXR [15,171–173]. In the same way, 6-(4-chlorophenyl)imidazo-[2,1-*b*][1,3]thiazole-5-carbaldehyde *O*-(3,4-dichlorobenzyl)oxime (CITCO) and 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene (TCPOBOP) are species-specific activators of CAR, with CITCO preferentially activating hCAR and TCPOBOP activating mCAR [15,171,174]. All four compounds are high affinity ligands for their preferred receptor, showing significantly lower or no affinity for the other species receptor. They are therefore commonly used as prototypical inducers of CYP3A4 (hPXR), Cyp3a11 (mPXR), CYP2B6 (hCAR), and cyp2b10 (mCAR), respectively, to validate models of P450 transactivation. With regard to AHR, a study by Westerink *et al.* identified differential CYP1A inducers between rat and human cell lines [175], while Boutros *et al.* also suggested that TCDD, although not affecting core AHR genes such as the CYP1 family, does exert species-specific effects, having a binding affinity for hAHR 10-fold less than that of mAHR, which could significantly

affect downstream regulation of target genes [176]. In view of the marked differences that can exist between ligand-induced regulation of drug metabolism, understanding how emerging drugs interact with human receptors before clinical testing is vital.

In order to address this issue, a number of new animal models have been created, which are humanized for the metabolic enzymes and transcription factors involved in drug metabolism [174,180,181]. Several approaches have been used in the construction of such models. Katoh *et al.* [181] created chimeric mice in which the innate hepatocytes of an immunocompromised mouse (uPA^{+/+}/SCID) were replaced with >90% human hepatocytes *in vivo*, resulting in an artificially humanized liver. However, the drawback of this model is that because these models must be produced as required, it requires a ready supply of human hepatocytes, which are both costly and hard to source as well as having the innate interindividual variability seen in the human population. The technique may also be restricted under legislation regulating the use of animals in experiments in some countries. A more common approach is to introduce the human gene into the mouse genome, either under the control of its own promoter by random integration or by replacing the endogenous mouse gene [174,180,182]. This has the advantage that the mouse lines can be continuously bred as well as potentially crossed to other mouse lines carrying linked genes of interest. This potentially expands the number of criteria that can be studied in a single model and helps overcome potential ethical and sourcing issues encountered with the chimeric models.

Many humanized models are now available, including a range of humanized P450 models, such as CYP2D6 and CYP3A4, to enable drug metabolism to be characterized. However, the key models from the perspective of P450 transcriptional regulation are those in which the transcription factors are humanized. Some of these models are reviewed by Stanley *et al.* [16] and Gonzalez and Shah [180]. A battery of PXR and CAR models have now been developed to allow PXR- and CAR-mediated P450 induction to be dissected [174,183,184]. These include a model in which both PXR and CAR have been replaced with the human genes under the control of the corresponding endogenous promoters, as well as models in which one receptor is humanized while the other is deleted. Together with more traditional single humanized and knockout models, these models have the potential to allow species specificity and the role of receptor cross talk in P450 induction to be fully analyzed. A further advantage of these models is that their design allows expression of PXR and CAR splice variants at physiologically relevant levels, allowing interindividual variability to be studied [183] (Section 8.8.3). These models therefore provide a powerful tool for use in the analysis of mechanisms underlying species-specific regulation of P450s. Although not perfect, with receptors still under the influence of the mouse physiological environment, the data that can be gained from these humanized models is more relevant to humans than traditional animal models, especially since the majority of species-specific activity is thought to depend on the sequence of the LBD. As these models become more complex, with multiple genes being humanized in one model, data quality is likely to improve.

8.3.3 Splice Variants

Alternative splicing of mRNA is ubiquitous in eukaryotes, and many human genes are subject to the process, with 86% having a minor isoform frequency of 15% or greater, resulting in the production of different mRNAs, thus potentially generating multiple proteins from a single gene and greatly increasing genomic diversity [185]. There are

a number of different mechanisms involved in alternative splicing of mRNA, including exon skipping, intron retention, and the use of alternative splice donor and acceptor sites [186,187].

Alternative splicing of human P450 mRNAs was first described in the 1980s [188]. However, the identification of splice variants of hCAR and hPXR was more recent. Different-sized hPXR mRNAs were first identified in the late 1990s [189,190], with Fukuen *et al.* describing a total of 9 hPXR SVs whose expression levels varied significantly across a panel of 15 liver samples [191]. Further work to define the expression of hPXR SVs found the most common variants to be PXR.2 (lacking 111 nt) and PXR.3 (lacking 123 nt), representing approximately 6.7% and 0.32%, respectively, of hPXR mRNA in human liver and also found in a number of other tissues, including brain, heart, colon, and bone marrow [3]. PXR.2 was subsequently reported not to function in a transactivation assay because of the failure of ligands to bind to the LBD in a productive manner, probably as a result of a change in protein structure and the continued binding of corepressors [192].

Choi *et al.* in describing murine CAR, also reported the existence of a variant mRNA (mCAR2), which lacked exon 8 and was unable to function in a transactivation assay [45]. The first SVs of the hCAR gene were reported in 2003 when Savkur *et al.* described an mRNA for hCAR with a 4-amino-acid insert between exons 6 and 7 and a 5-amino-acid insert between exons 7 and 8 resulting from the use of alternative splice acceptor sites, and another with a complete deletion of exon 7 and loss of 39 amino acids [193]. In addition to these variants, Auerbach *et al.* [194] reported further hCAR SVs with one or other of the insertions between exons 6/7 and 7/8 and confirmed that such variants had compromised function. The range of hCAR SVs was extended dramatically when Lamba *et al.* reported 22 unique mRNAs from a panel of human liver and other tissues [195]. Several of these SVs had premature termination codons and failed to produce protein, but many had significant deletions or insertions, yielding proteins significantly different in size from the wild-type, or reference, form and which had altered N- and/or C-terminal amino acids. The hCAR SVs were differentially expressed, with only the hCAR reference form found in the intestine, whereas spleen, heart, and prostate expressed only the SVs, and were nonfunctional in transactivation assays, although the authors speculated that such SVs might possess biological function(s) yet to be identified [195]. A biological function was demonstrated for the hCAR SV with a 5-amino-acid insertion between exons 7 and 8, termed CAR3 by Auerbach *et al.*, who found activity in a transactivation assay with an optimized 3× DR4 reporter using CITCO, thus defining CAR3 as a ligand-activated receptor in contrast to the reference form (CAR1) [196]. The same group further demonstrated that CAR2, with a 4-amino-acid insertion between exons 6 and 7, displayed a regulatory response distinct from that of CAR1, speculating that the ligand-binding pocket may be modified by the additional residues found in CAR2 [197]. Subsequently, CAR2 was also shown to be a ligand-activated receptor present in approximately 30% of total CAR transcripts in human hepatocytes and uniquely responsive to the plasticizer di(2-ethylhexyl) phthalate (DEHP) [198]. These latter findings—that a nuclear receptor present at significant levels in human liver (but absent in other animal models) is highly responsive to a chemical agent commonly found in a wide range of everyday materials, including medical devices—have potentially significant implications for safety testing in general and predictive human toxicity in particular.

To address these concerns, a unique panel of transgenic mice humanized for CAR and/or PXR have been generated, which are nulled for murine CAR and PXR and express the reference forms and two major SVs of hCAR (CAR2 and CAR3) and hPXR (PXR2 and PXR3) under the control of the endogenous mouse promotor [174]. Expression levels of the CAR and PXR SVs in these mouse models were comparable to that found in a panel of human livers, with the exception of hPXR2 in which the expression was approximately fourfold higher in the transgenic mouse [183]. The expression profile of the PXR SVs in the hPXR mouse found that PXR1 was expressed in a range of tissues at varying levels—liver > small intestine > kidney > lung > gonads > brain—while PXR2 was expressed, as a % of total PXR mRNA, at approximately the same level in all tissues, and PXR3 at highest levels in the kidney, gonads, and brain (Bower, CCM, unpublished observations). These mouse models provide a useful tool to investigate the role of CAR and PXR in drug metabolism, disposition, and efficacy in humans.

8.3.4 Genetic Polymorphisms

Interindividual variation in human drug metabolism is a significant cause of variability in drug response [199]; a main contributor is genetic polymorphism [200]. P450s are a highly polymorphic group of enzymes, with more than 350 different functional alleles so far identified in the genes, accounting for 40–50% of P450-dependent metabolism in humans [201,202]. Most of the characterized polymorphisms are variations in the coding sequence, such as SNPs, deletions, or gene amplifications [203,204]. They can, however, also be in gene promoters or intronic regions, which interfere with transcription factor binding or cause alternative or aberrant mRNA splicing [202,204]. Many of these polymorphisms manifest themselves as enzymes possessing altered activity [201]. One example of this is seen in the *CYP2B6**6 polymorphic isoform, which possesses two SNPs, 516Gly > Thr and 785Ala > Gly [59]. These substitutions result in alternative gene splicing, yielding a product with a deletion of exons 4–6 and that displays a significant reduction in catalytic activity and protein expression relative to the reference *CYP2B6**1. Presence of these polymorphic variants can therefore significantly affect downstream drug metabolism.

Another source of interindividual variability in P450 expression is the polymorphisms in their regulators. One such polymorphic regulator is PXR, with 373 SNPs having been identified, and many of these proving to be functional [205,206]. As an example of the effect of PXR polymorphism on downstream gene expression, a study by Wang *et al.* [205] has examined the effect of two haplotypes of PXR commonly found in the Han Chinese population, H1 (TCAGGGGCCACC) and H2 (CCGAAAAC-TAAT), on P450 expression, using CYP3A4 activity as a marker. They found that those with the haplotype pair H1/H1 had much higher inducible CYP3A4 metabolic activity than those subjects with the H1/H2 and H2/H2 pairings following treatment with St Johns' Wort, as indicated by the significant differences in AUC_{0-t} and $AUC_{0-\infty}$ for the CYP3A4 probe drug nifedipine and its metabolite, dehydronifedipine. This phenomenon has been further confirmed by identification of functional polymorphisms in the FOXA2 transcription factor, which affect *CYP3A4* transcription and are also linked to diseases, such as type II diabetes [207]. Polymorphisms in P450s and the transcription factors, which control their expression, can therefore play a significant role in interindividual variation in xenobiotic metabolism. Understanding the genetic differences in P450 regulation remains an important subject for future study.

8.4 CONCLUSION

The adaptive response system that has been evolved by organisms to protect the cell from the many forms of toxic insult plays a central role in the metabolism and disposition of drugs. The importance of this system is underlined by its robust nature and built-in functional redundancy that allows at least a partial response in the absence or failure of a component part. The species differences observed in the regulation of P450 expression underline the importance of developing relevant models to test for human drug safety and efficacy, and in which factors such as gender, circadian rhythm, diet may also be taken into account. It is thus clear that an understanding of how drug metabolism is regulated, and the multitude of variable factors involved, is crucial to the optimal application of drug treatments and minimization of unwanted side effects and drug–drug interactions.

ABBREVIATIONS

AF-2	Activation Function 2
AHR	Aryl Hydrocarbon Receptor
AP-1	Activator Protein 1
ARNT	Aryl Hydrocarbon Receptor Nuclear Translocator
bHLH	Basic Helix-Loop-Helix
bp	Base Pair
cAMP	cyclic AMP
CAR	Constitutive Androstane Receptor
CCRP	Cytoplasmic CAR Retention Protein
Cdk2	Cyclin-Dependent Kinase 2
C/EBP α	CCAAT/Enhancer Binding Protein α
ChIP	Chromatin Immunoprecipitation
CHIP	C-terminal of HSP70 interacting protein
CITCO	6-(4-Chlorophenyl)imidazo[2,1- <i>b</i>]thiazole-5-carbaldehyde <i>O</i> -(3,4-dichlorobenzyl)oxime
CLEM4	Constitutive Liver Enhancer Module of CYP3A4
CREB	cAMP Response Element Binding Protein
CYP	Cytochrome P450
DBP	Albumin D-Box Binding Protein
DEHP	Di(2-ethylhexyl) Phthalate
DR	Direct Repeat
EGR1	Early Growth Response 1
GR	Glucocorticoid Receptor
GRE	Glucocorticoid Response Elements
HIF1 α	Hypoxia Inducible Factor 1 α
HLF	Hepatic Leukemia Factor
HNF1	Hepatic Nuclear Factor 1
HNF3 β	Hepatic Nuclear Factor 3 β
HNF3 γ	Hepatic Nuclear Factor 3 γ
HNF4 α	Hepatic Nuclear Factor 4 α
LBD	Ligand-Binding Domain

LBP	Ligand-Binding Pocket
NCOA6	Nuclear Receptor Coactivator 6
NCoR	Nuclear Receptor Corepressor
NF1	Nuclear Factor 1
NLS	Nuclear Localization Signal
nt	Nucleotide
OARE _{KI}	Okadaic Acid Response Element
P450	Cytochrome P450
PAS	PER-ARNT-Sim
PB	Phenobarbital
PBREM	Phenobarbital-Responsive Enhancer Module
PCN	Pregnenolone-16 α -carbonitrile
PDE4A5	Phosphodiesterase 4A5
PGC1 α	Peroxisome-Proliferator-Activated Receptor Gamma Coactivator 1-Alpha
PIMT	PRIP-Interacting Protein with Interacting Methyltransferase Domain
PKA	Protein Kinase A
PP2A	Protein Phosphatase 2A
PRIP	Peroxisome-Proliferator-Activated Receptor (PPAR)-Interacting Protein
PXR	Pregnane X Receptor
PXRE	PXR-Response Element
RIF	Rifampicin
ROR	Retinoic-Acid-Receptor-Related Orphan Receptor
RT-PCR	Reverse Transcription Polymerase Chain Reaction
RXR	Retinoid X Receptor
SMRT	Silencing Mediator of Retinoid and Thyroid Hormone Receptor
SNP	Single Nucleotide Polymorphism
Sp1	Specificity Protein 1
SRC	Steroid Receptor Coactivator
STAT1	Signal Transducers and Activators of Transcription 1
SV	Splice Variant
TAD	Transcription Activation Domain
TCDD	2,3,7,8-Tetrachlorodibenzo- <i>p</i> -dioxin
TCPOBOP	1,4-Bis[2-(3,5-dichloropyridyloxy)]benzene
TEF	Thyrotroph Embryonic Factor
TR	Thyroid Receptor
USF-1	Upstream Stimulatory Factor 1
VDR	Vitamin D Receptor
XAP2	X-Associated Protein 2
XRE	Xenobiotic Response Element
XREM	Xenobiotic Responsive Enhancer Module

9.1 SUMMARY

The majority of drugs in clinical use undergo oxidative biotransformations catalyzed by cytochrome P450 (CYP) enzymes. Approximately one dozen isoforms of the CYP families 1, 2, and 3 are mainly responsible for the metabolism of drugs and other xenobiotics. The typically large interindividual variability of these enzymes is an important determinant of drug pharmacokinetics and drug response. Both genetic and nongenetic factors contribute to this variability, but the degree to which genetic polymorphism plays a role in determining expression and function is different for each individual P450 gene. This chapter summarizes the enormous body of experimental evidence that has been gathered on the functional, clinical, and toxicological relevance of P450 genetic polymorphism. In the family CYP1, the *CYP1A1*, *CYP1A2*, and *CYP1B1* genes encode enzymes with preference for polycyclic and heterocyclic aromatic compounds. *CYP1A2* is expressed at higher levels in liver, whereas CYPs 1A1 and 1B1 are mostly extrahepatic enzymes. While *CYP1B1* mutations are causally involved in the development of congenital glaucoma, genetic polymorphism in the CYP1 family is of inferior significance for drug metabolism compared to nongenetic factors. In the largest human family CYP2, five subfamilies are of particular importance. Of the CYP2A genes *CYP2A6*, *CYP2A7*, and *CYP2A13*, the *CYP2A6* polymorphism is an established determinant of nicotine metabolism with influence on addictive behavior. *CYP2B6*, the only functional enzyme encoded in the CYP2B subfamily, is highly polymorphic, and slow metabolizer genotypes are frequent among all major ethnic groups. The *CYP2B6* polymorphism is important for HIV therapy with the antiretroviral drug efavirenz. The CYP2C subfamily comprises the four expressed genes *CYP2C8*, *CYP2C9*, *CYP2C18*, and *CYP2C19*. Despite their high homology, these genes differ tremendously with respect to expression, regulation, substrate selectivity, and genetic

polymorphism. Clear genotype–phenotype correlations are established for CYP2C19 and CYP2C9. The historical polymorphism of *S*-mephenytoin hydroxylation, which is caused by loss-of-function alleles more prevalent among Asians than in other ethnic groups, recently gained importance for additional drugs. The polymorphism of CYP2C9 comprises amino acid variants that can have differential effects depending on the substrate and is of high clinical relevance. The strong genotype–phenotype correlation of CYP2D6 is in part due to the lack of gene regulation such as induction and on the existence of numerous single nucleotide polymorphisms (SNPs) and larger structural variations, including gene deletions, duplications, and recombinations. This results primarily in different expression levels leading to the ultrarapid metabolizer (UM), extensive metabolizer (EM), intermediate metabolizer (IM), and poor metabolizer (PM) phenotypes, the frequencies of which depend on ethnic background. The enzyme has a broad substrate selectivity comprising up to 20% of all drugs on the market. In contrast, CYP2E1, an ethanol-inducible P450, has a preference for low molecular weight compounds especially relevant for toxicological processes, which are only marginally influenced by genetic polymorphism. Often cited as the most important P450 subfamily, CYP3A comprises four functional genes, the most abundant and highly drug-inducible *CYP3A4* and the minor forms *CYP3A5*, *CYP3A7*, and *CYP3A43*. For *CYP3A4*, only few polymorphic markers of controversial value exist. *CYP3A5* and *CYP3A7* are polymorphically expressed but are of limited clinical importance because of their lower expression.

9.2 INTRODUCTION—SIGNIFICANCE OF P450 POLYMORPHISMS AND PHARMACOGENETICS

The human genome comprises 57 putatively functional, protein-coding CYP genes and 58 pseudogenes compared to 102 putatively functional genes and 88 pseudogenes in the mouse [1]. The human genes are grouped according to their sequence similarity into 18 families and 44 subfamilies (<http://drnelson.utmem.edu/human.P450.table.html>). The CYP1, 2, and 3 family isozymes have broad and overlapping substrate specificities, which usually provides for a robust elimination of lipophilic xenobiotics, including most drugs in clinical use [2–4]. In contrast, the CYPs of families CYP4 to CYP51 are mainly involved in endogenous metabolic pathways of steroids, fatty acids, prostaglandins, retinoids, and others [5]. The CYP1–CYP3 family isozymes show extremely variable expression and function, typically exceeding 100-fold within a given population sample, which leads to unforeseen drug responses including overreaction, toxicity, or lack of response in a considerable fraction of patients who have been treated with drug substrates of these enzymes. The reasons for this high interindividual and intraindividual variability include environmental influences such as drug–drug interactions, biological factors including sex and circadian rhythm, physiological determinants such as disease and hormonal status, and genetic polymorphisms in CYP genes and their regulators [3,4,6]. Genetic polymorphisms, although present in practically all human genes, affect only some CYP isoforms to a functionally relevant extent, including, in particular, CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2D6, and the minor CYP3A forms CYP3A5 and CYP3A7. On the contrary, the highly abundant liver enzymes CYP1A2 and CYP3A4 are not functionally polymorphic because the known sequence variants only marginally affect their expression or function. The focus of this chapter is

to provide a summary of the medical relevance of the most important drug-metabolizing human CYPs of families CYP1, CYP2, and CYP3, with special emphasis on functionally relevant polymorphisms and their role in the metabolism of clinically relevant drugs. The numerous *in vitro* and *in vivo* pharmacogenetic studies that have been published on the subject illustrate the complex biology of these polymorphic genes at the level of basic mechanisms (*null* alleles, partially functional alleles, substrate-dependent effects, linkage disequilibrium, etc.) as well as their pharmacological, toxicological, and clinical relevance (PD (pharmacodynamics) vs PK (pharmacokinetics), adverse reactions, prodrugs, etc.). The website of the cypallele nomenclature committee served as the basis for naming variant alleles, and the reader is referred to this site for more detailed coverage of literature regarding individual allele variants ([7]; available at <http://www.cypalleles.ki.se>; consulted April 2010).

9.3 HUMAN DRUG-METABOLIZING CYTOCHROME P450s

9.3.1 Family *CYP1* — Overview

The human *CYP1A* family contains three functional genes in two subfamilies *CYP1A* and *CYP1B*. The highly conserved *CYP1A1* and *CYP1A2* genes, both of which consist of seven exons and six introns, are located on chromosome 15q24.1, whereas *CYP1B1* is located on chromosome 2p22.2 and contains three exons and two introns [1]. Many of the CYP1 substrates are ligands to the aromatic hydrocarbon receptor (AhR) that positively regulates the expression of *CYP1* and a battery of other genes in a coordinated manner at the transcriptional level [8,9]. The *CYP1A1* and *CYP1A2* genes are oriented head to head with a shared bidirectional promoter in between, which contains at least 13 AhR response elements [10]. Despite their common AhR-dependent regulation, the ontogenic patterns differ substantially, in that *CYP1A1* is expressed more during embryogenesis, whereas *CYP1A2* only appears around birth [11]. Pharmacologically most relevant is *CYP1A2*, which is constitutively expressed in liver, where it contributes on average ~10–15% to the total microsomal P450 pool, but it is also expressed in intestine, pancreas, lung, and brain. *CYP1A2* appears to display higher activity in men than in women [12,13]. Constitutive expression of *CYP1A1* in liver is low, but inducible expression triggered by environmental inducers such as cigarette smoke, dioxin, and polycyclic hydrocarbons occurs ubiquitously in all tissues including lung and breast [14]. *CYP1B1* is an extrahepatic enzyme expressed predominantly in various tumors and a useful tumor marker because of its absence in the corresponding normal tissues [15]. Notably, *CYP1B1* is also expressed in various cell types of the human and mouse eye, where it has a yet undefined developmental role [16].

The substrates of the CYP1 enzymes include many polycyclic and other aromatic substances including diverse procarcinogens such as arylarenes, nitroarenes, and arylamines to reactive metabolites such as epoxide intermediates, which are carcinogenic in experimental animals and humans because they can cause DNA damage. Activation of the carcinogen benzo[*a*]pyrene is an important example of this type of metabolic activation [14]. *CYP1A2* shows a preference for aromatic amines and heterocyclic compounds, including the two prototypic substrates theophylline and caffeine. Endogenous substrates are also known, for example, prostaglandins, estrogens, melatonin, and retinoic acid, some of which appear to affect the phenotype of *Ahr*^{-/-} knockout mice

[17]. Only CYP1A2, because of its high expression in liver, metabolizes a significant number of clinically important drugs, including acetaminophen, phenacetin, lidocaine [18], and the CNS drugs olanzapine, clozapine, and duloxetine, among others [19,20]. Also of clinical importance is the fact that CYP1A2 is sensitive to drug interactions because of reversible and/or irreversible inhibition and induction by numerous drugs and several other xenobiotics. The structure of human CYP1A2 in complex with the inhibitor α -naphthoflavone was recently presented at a resolution of 1.95 Å, revealing a compact active site cavity highly adapted for the positioning and oxidation of relatively large, planar substrates [21]. CYP1B1 has catalytic activities overlapping with CYP1A1 and CYP1A2 and also catalyzes activation of diverse procarcinogens, but the catalytic role depends on the substrate and the expression level in each tissue [22].

9.3.1.1 Subfamily *CYP1A*—*CYP1A1* and *CYP1A2*.

9.3.1.1.1 *CYP1A1*. The *CYPAllele* website lists 10 variant alleles and a number of subvariants, as well as additional SNPs, where the haplotype has not yet been determined. Four early identified, more common variants were originally termed m1–m4. The m1 variant (*CYP1A1**2A), which harbors a 3698 T>C transition creating a new MspI site downstream of the polyadenylation site, and the m2 variant (*CYP1A1**2C) with the key mutation Ile462Val near the heme-binding region were associated with greater enzymatic activity in some but not all studies [14,23]. These variants are common among Asians (~35% and 20%, respectively, Table 9.1) and have been proposed as genetic susceptibility factors for lung cancer in the Japanese [24,25], but this finding was not confirmed in other populations, possibly because of the much lower allele frequencies [26]. The m3 variant (*CYP1A1**3 creating an MspI site in the 3' noncoding region) appears to be an African-specific mutation that does not occur in the other large ethnicities. The m4 variant is located near the m2 mutation site and codes for an amino acid change (Thr461Asn) near the heme-binding region. Its frequency is quite low (~3%) in Caucasians, and no association with lung cancer was found [26]. Besides these variants, other coding polymorphisms (in total to 16 amino acid variants) were described but functional data is scarce.

Because many *CYP1A* substrates are procarcinogens occurring in industrial combustion products, cigarette smoke, and charred food, polymorphisms in the human *CYP1A* family genes have been investigated mostly as risk factors for various forms of cancer including breast and lung cancer. The evidence for association of *CYP1A1* polymorphisms with cancer is controversial, as some studies reported increased susceptibility, whereas others have reported no relationship, although most experimental data support positive associations for the more common variants [27–33]. Further investigation is required with larger clinical studies, consideration of environmental and other non-genetic factors, more detailed haplotype analysis, as well as a more rigorous functional assessment of the variants.

9.3.1.1.2 *CYP1A2*. Like other drug-metabolizing enzymes, *CYP1A2* expression in human liver is highly variable between individuals, which is certainly due to several factors including genetic, epigenetic, and environmental factors (e.g., smoking [34]). By measuring the caffeine metabolic ratio as a *CYP1A2* activity marker in a large cohort ($n = 378$) of mono- and dizygotic twins selected to exclude the influence of smoking, oral contraceptives, and gender, Brøsen and colleagues found a strong overall heritability of 0.72 [35]. To date, more than 15 variant alleles and numerous haplotype variants

^b Genomic positions are given.

^c Frequencies of the indicated variant alleles were obtained for different ethnicities (AA, African-American; Af African; As, Asian; Ar, Arab; Ca, Caucasian; Hs, Hispanic; In, Indian; Pc, Pacific; SA, South American) from dbSNP at <http://www.ncbi.nlm.nih.gov/SNP>, from the Allele Frequency Database (ALFRED) at <http://alfred.med.yale.edu/alfred/index.asp>, and from the references indicated in the text.

of the *CYP1A2* gene have been defined, and some of them have been associated with altered drug clearance and response and with disease susceptibility. However, it appears that the basis for inheritable CYP1A2-dependent phenotypes has not been satisfactorily elucidated. In a recent study, the human *CYP1A1-CYP1A2* locus was resequenced in 5 major ethnicities phenotyped, revealing a total of 85 SNPs, 57 of which occurred more than once [36]. Attempts to relate the most common of these SNPs to phenotype in genotyped volunteers were disappointing, and it was concluded that no SNP or haplotype in the *CYP1A2* gene has a clear predictive value [37]. Among the polymorphic sites in the coding and noncoding regions in the *CYP1A2* gene, only few common SNPs are currently considered to be of potential predictive value, including the 5'-upstream variant -3860G>A (*CYP1A2*1C*) and the intron 1 polymorphism -163C>A (*CYP1A2*1F*) located downstream of the untranslated first exon. Functional evidence for the *CYP1A2*1C* variant suggests decreased inducibility by smoking on the basis of promoter analyses and its association with decreased caffeine 3-demethylation in Japanese smokers [38]. In contrast to the **1C* variant, the intron 1 variant, *CYP1A2*1F*, was associated with increased enzyme inducibility in German [39] and Swedish [34] smokers and with "ultrarapid" caffeine metabolism and nonresponse to clozapine in smoking patients with schizophrenia [40]. The opposite effect of the two variants is consistent with the findings that carriers of the combined genotype *CYP1A2*1C/*1F* were not induced by omeprazole [41]. The *CYP1A2* genotype also modifies the risk of hypertension in coffee drinkers, who were at increased risk when they carried the slow **1F* allele [42]. Although slower metabolism of caffeine was confirmed in Chinese breast cancer patients, the variant was not related to disease risk [43]. However, some data with different substrates are contradictory, as no influence was found for clozapine [44], haloperidol [45], and trazodone [46]. These discrepancies may be due to ethnically diverse haplotype patterns.

CYP1A2 polymorphisms that lead to amino acid changes are generally rare, but for some of them, decreased activity could be shown in recombinant expression systems. The Arg431Trp substitution (*CYP1A2*6*), which is located in the "meander" peptide, a region critical for maintenance of protein tertiary structure, was shown to interfere with binding and to result in nonfunctional protein [47]. However, because of their rare occurrence, this and other amino acid variants [7] are of limited clinical use. In Chinese subjects phenotyped with caffeine, a common haplotype containing the novel SNP -3113G>A was associated with significantly lower metabolic activity. This SNP is located in a proposed regulatory element, but it remained unclear whether it is causally responsible for the effect [48].

In conclusion, the currently known polymorphisms in the *CYP1A2* gene explain only a small fraction of the *CYP1A2* expression and functional variability. Although novel SNPs may still be discovered, genetic determinants in other genes that contribute to the regulation of *CYP1A2* expression, including the AhR pathway, inflammation signaling pathway, or other signaling pathways, may be involved. Although AhR polymorphisms were reported [49,50], systematic investigations and an evaluation of their effects on *CYP1A2* phenotypes are scarce.

9.3.1.2 Subfamily *CYP1B*—*CYP1B1*. *CYP1B1* is the first CYP that was shown to be involved in a primary developmental defect if mutated. It was identified by genetic linkage analysis and mutation studies as a causative gene in primary congenital glaucoma, an inheritable neurodegenerative disease leading to blindness [51].

Because CYP1B1 may be involved in the metabolism of steroids, arachidonic acid, vitamin A, and melatonin, the enzyme is believed to be responsible for the generation of an as yet undefined signaling molecule(s) that is somehow involved in the development and pathogenesis of glaucoma. Over 80 mutations have been identified in patients with various forms of glaucoma [51]. Most of them are missense or nonsense mutations, or deletions, insertions, and/or duplications. Some of them are predicted to interrupt the open reading frame, and some were shown to lead to severely compromised enzyme function [51–54]. Because these mutations are rare in the general population, their value as tumor markers or markers of altered metabolism of drugs may be limited.

At least six more common polymorphic alleles, which contain five amino acid changes in different combinations, also exist in the *CYP1B1* gene. Functional analysis of four variant proteins coexpressed with P450 reductase in *Escherichia coli* revealed little influence of the Arg48Gly, Ala119Ser, and Asn453Ser variants on kinetic properties toward 17 β -estradiol as substrate, but a threefold increase in K_m for the Leu432Val (*CYP1B1**3) variant [55]. An expression study in yeast found contradictory data regarding the Leu432Val variant, in that no change was seen for the individual variant using the same substrate but decreased V_{max} and increased K_m values toward 17 β -estradiol when additional amino acid changes were present in the CYP1B1.6 and CYP1B1.7 alleles [56]. The CYP1B1.7 variant was also shown to have decreased capacity to hydroxylate benzo[*a*]pyrene. The Leu432Val variation was also correlated to changed urinary estrogen metabolites, indicating *in vivo* contribution of CYP1B1 to catabolism of estrogen [57]. These functional *in vitro* studies suggest that these common amino acid changes in the *CYP2B6* gene lead to little or moderate but potentially substrate-dependent changes in the catalytic properties of the enzyme.

Association of *CYP1B1* genotype with various forms of cancer was reported including a possible effect on breast cancer risk in Caucasians but not in Asians [58]. Regarding three further *CYP1B1* polymorphisms resulting in amino acid changes Arg48Gly, Ala119Ser, and Asn453Ser, a recent meta-analysis concluded that these polymorphisms are not associated with breast cancer risk [59]. In a large study that included more than 10,000 patients, *CYP1B1* variants *3 [Leu432Val] and *4 [Asn453Ser], which influence the metabolism of polycyclic aromatic hydrocarbons of tobacco smoke, were also not associated with the risk of various diseases including chronic obstructive pulmonary disease and tobacco-related lung cancer [60].

9.3.2 Family CYP2—Overview

The *CYP2* family is the largest family in humans. It contains 16 full-length genes and all have 9 exons and 8 introns. Among them are most of the important drug-metabolizing CYPs expressed in liver as well as several extrahepatic enzymes, for some of which the function has yet to be elucidated (“orphan” CYPs [61]). The genes are organized in a number of multigene clusters that can contain one or more subfamilies and are spread over different chromosomes. The three largest gene clusters are the *CYP2ABFGST* cluster on chromosome 19q13.2, the *CYP2C* cluster on chromosome 10q23.33, and the *CYP2D* cluster on chromosome 22q13.1–2. In the evolution of rodents, many of the *CYP2* subfamilies expanded tremendously, making direct comparisons between mouse and human P450s especially challenging in this family [1].

Almost all *CYP2* genes are highly polymorphic. This chapter describes those genes that are of highest importance for xenobiotic metabolism.

9.3.2.1 Subfamily *CYP2A*—*CYP2A6*, *CYP2A7*, and *CYP2A13*.

9.3.2.1.1 Molecular Genetics and Pharmacological Properties. The human *CYP2A* genes are part of a 350-kb *CYP2ABFGST* gene cluster on chromosome 19q13.2 that contains genes and pseudogenes of the *CYP2A*, *2B*, *2F*, *2G*, *2S*, and *2T* subfamilies [1]. It contains the four *CYP2A* members *CYP2A6*, *CYP2A7*, *CYP2A13*, and a split pseudogene *CYP2A18P*. In humans, *CYP2A6* is mainly expressed in the liver where it represents on average about 2% of the total liver P450 protein, whereas in extrahepatic tissues, it was found only in trace amounts. *CYP2A7* is a nonfunctional enzyme that is unable to incorporate and exhibit catalytic activity in various heterologous systems [62]. *CYP2A13* codes for a catalytically active protein and is predominantly expressed in the respiratory tract, where expression levels decrease from nasal mucosa to peripheral lung tissues [63,64].

Human *CYP2A6* has been recognized as the major isoform involved in the oxidative metabolism of the psychoactive tobacco ingredient nicotine to the inactive cotinine [65,66]. A rather specific marker activity for *CYP2A6* is the 7-hydroxylation of coumarin [67,68]. Up to 300-fold interindividual differences in *CYP2A6*-mediated coumarin 7-hydroxylase activity were observed, which is influenced by ethnicity, as only 1% of white subjects are PMs compared to up to 20% of Asians [69,70]. *CYP2A6* is also the main isoenzyme responsible for the minor 7-hydroxylation of efavirenz [71]. Furthermore, *CYP2A6* contributes to the metabolism of a number of clinically used drugs such as disulfiram, fadrozole, halothane, letrozole, losigamone, methoxyflurane, and valproic acid [72]. *CYP2A13* has similar substrate specificity and also metabolizes coumarin and nicotine, but it has been shown to be the most efficient metabolic activator of nicotine-derived nitrosamine ketone (NNK), a major tobacco procarcinogen [73].

9.3.2.1.2 Genetic Polymorphisms and Pharmacogenetics. Genetic variation in the *CYP2A6* gene can both increase or decrease enzyme activity because it includes alleles with deleted or duplicated genes, gene conversions, nucleotide deletions and insertions, as well as numerous coding and noncoding SNPs. These variants may change mRNA and/or protein expression levels or affect the structure and function of the protein [74,75]. The CYPAllele website currently lists 37 distinct alleles, that is, variants that cause amino acid changes or with proven functional effect. Many of these variants occur in various combinations, giving rise to complex haplotypes that occur at distinct ethnic frequencies [76]. A detailed compilation of the known structural changes and their functional impact was presented by Mwenifumbo and Tyndale [74]. The prevalence of functionally relevant *CYP2A6* alleles was recently estimated to be ~9% in Caucasians, ~22% in Africans, and up to 50% in Asians [77].

The *CYP2A6**2 [Leu160His] and the *4A-*H* deletion alleles have been shown to dramatically reduce enzyme activity *in vivo* in homozygous or hemizygous combination, resulting in the PM phenotype in affected individuals (Table 9.1). The most frequent of these presumable *null* alleles in Asians are the *4A-*H* hybrid-deleted alleles that consist of a *CYP2A7*-derived 5' part and a 3' part of *CYP2A6* origin. The *4A deletion variant is rare in Caucasians and Africans but present with up to ~20% frequency in Asian populations [76]. The *CYP2A6**2 [Leu160His] codes for an unstable

protein that fails to incorporate heme, but its frequency is only ~1% to 5% in Caucasians and is lower in Africans and Asians [76]. In a study involving 156 liver samples from Caucasians, resequencing revealed 33 haplotypes of which two (*9B, containing a -48T>G TATA-box polymorphism, and the 2A7/2A6 recombination allele *12B) were major genetic determinants associated with decreased hepatic expression [78].

A number of additional alleles including *CYP2A6**7, *10, and *17 severely reduce enzyme activity in homozygous or hemizygous individuals. The *7 [Ile471Thr] and *10 [Ile471Thr; Arg485Leu] alleles are Asian specific, and *17 [Val365Met] was only found in African-Americans. The *CYP2A6**5, *6, *11, *19, and *20 alleles were shown to have reduced activity by heterologous expression, but their low frequencies did, so far, not allow to confirm this *in vivo*. A further number of variants were shown to affect expression or function less dramatically, including several promoter variants that result in decreased expression, and some variants have not been characterized yet [74]. The *CYP2A6* gene was found in a duplicated variant in at least two different allele variants (*1X2A and *1X2B), which appear to be correlated to increased activity [79,80]. A decreased gene copy number is associated with gene deletions of the *CYP2A6**4A-4H alleles.

Most pharmacogenetic studies involving *CYP2A6* were carried out to study the effect of genotype on nicotine metabolism, smoking behavior, or lung cancer risk.

An *in vivo* study in 278 healthy Caucasian volunteers investigated the relationship between variant *CYP2A6* genotypes and the disposition and metabolism of intravenously administered nicotine [81]. Genotype-dependent differences in nicotine and cotinine plasma clearance were observed with the group, including the normal activity alleles having the largest capacity for nicotine C-oxidation. In a nicotine-replacement clinical trial, the group with slow metabolizer alleles had 50% reduced *CYP2A6* activity before treatment and reached 44% higher steady-state plasma levels of nicotine [82]. A large interethnic variability study compared nicotine metabolism and *CYP2A6* genotype in white, black, Korean, and Japanese subjects [76]. Large interindividual differences were observed in the cotinine/nicotine ratios in plasma. While no difference was found in the metabolic ratio of white, black, and Korean subjects, Japanese subjects showed a significantly lower metabolic ratio. The influence of low activity alleles on nicotine metabolism was confirmed in this study.

In contrast to the influence on pharmacokinetics, association of genetically variant *CYP2A6* with smoking behavior or lung cancer risk is still debated. The reader is referred to recent specialized reviews on these topics [74,75,83].

CYP2A6 polymorphism also plays a role for other substrates. A recent study emphasized the role of *CYP2A6* for efavirenz, an antiretroviral drug usually metabolized by *CYP2B6* to the 8-hydroxyderivative. As initially shown in human liver microsomes, the minor 7-hydroxy-efavirenz metabolite is mainly formed by *CYP2A6* [71]. The wide interindividual variability in efavirenz plasma exposure is largely explained by *CYP2B6* polymorphisms (see below). However, in patients with genetically impaired *CYP2B6*, substrate flux via the *CYP2A6*-dependent pathway is increased. The accessory metabolic pathway was shown to be critical in limiting drug accumulation in individuals characterized as *CYP2B6* slow metabolizers [77]. As combined *CYP2B6* and *CYP2A6* genetic deficiency occurs at significant frequency in various human populations, the *CYP2A6* polymorphism may be a clinically relevant determinant of extremely high efavirenz exposure in HIV patients.

9.3.2.2 Subfamily CYP2B—CYP2B6.

9.3.2.2.1 Molecular Genetics and Pharmacological Properties. The human *CYP2B* subfamily consists of the functional *CYP2B6* gene and the nonfunctional pseudogene *CYP2B7P*, which are located in a tandem head-to-tail arrangement within the large *CYP2ABFGST* gene cluster on chromosome 19 [1]. Expression of human CYP2B6 was initially underestimated [84], but despite higher estimations of more recent studies, it is one of the weaker expressed P450s, contributing on average ~2% to the total hepatic P450 pool [85]. CYP2B6 is also detectably expressed in human brain, kidney, heart, intestine, uterine endometrium, skin, and various tissues of the respiratory tract, including lung and nasal mucosa [64,86,87].

The CYP2B6 enzyme metabolizes diverse chemicals including several clinically used drugs as well as a large number of environmental chemicals. Therapeutically important drug substrates include the prodrug cyclophosphamide, which is activated by CYP2B6 to the cytotoxic 4-hydroxy-metabolite; the antiretroviral drugs efavirenz and nevirapine; the antidepressant and smoking cessation agent bupropion; the benzodiazepine diazepam; the antimalarial artemisinin; the anesthetics propofol and ketamine; and the synthetic opioid methadone [88–90]. Several suitable probe drugs for CYP2B6 have been discussed, but bupropion hydroxylation appears to be the most selective one [91] and is now most often used. However, because bupropion hydroxylation is not a sensitive marker for pharmacogenetic differences *in vivo* [92], other biotransformations may be more suitable markers. Liver microsomal efavirenz 8-hydroxylation has been shown to be correlated to CYP2B6 protein amount and is highly dependent on genotype *in vivo* (see below). Its usefulness as a suitable probe drug for CYP2B6 has, however, not yet been formally shown. CYP2B6 also metabolizes the N-demethylation of the recreational drug ecstasy (MDMA), which leads to potentially neurotoxic metabolites [93]. Nondrug xenobiotics metabolized mainly by CYP2B6 include the organophosphorus insecticide chlorpyrifos, which is metabolized to the more toxic oxon metabolite; the insecticide and endocrine disruptor methoxychlor; and the extensively used insect repellent DEET (*N,N*-diethyl-*meta*-toluamide) (for review, see Ref. 94).

Hepatic CYP2B6 is highly variable. In our study of 235 human liver samples, CYP2B6 protein varied ~360-fold, and all samples expressed at least a very low amount of the protein [85,95]. In this and other studies [96], no significant sex difference in CYP2B6 expression was found, but the issue remains controversial as other studies reported gender differences with higher expression in females versus males, which were more pronounced among Hispanics than Caucasians [97]. Several other mechanisms have been shown to contribute to inter- and intraindividual variability in hepatic CYP2B6 function, including induction of transcription by xenobiotics, [98] reversible and irreversible inhibition by diverse substances, [89] and genetic polymorphism [95]. As the human ortholog to the rodent phenobarbital-inducible CYP2b9/2b10 enzymes, CYP2B6 induction by drugs and other xenobiotics is due to similar mechanisms involving the xenosensors constitutive androstane receptor (CAR) and/or the pregnane X receptor (PXR) [98–100]. Known inducers are, for example, rifampin, barbiturates, cyclophosphamide, artemisinin, carbamazepine, efavirenz, and nevirapine, as well as metamizole [99,101] and statins [102]. Although this environmentally triggered variability should be expected to mask pharmacogenetic phenotypes, *CYP2B6* polymorphisms turned out to be highly significant for pharmacokinetics and possibly response to certain drugs, in particular, the anti-HIV drug efavirenz.

9.3.2.2.2 Genetic Polymorphisms and Pharmacogenetics. The CYPallele website currently lists 29 distinct alleles, that is, variants that cause amino acid changes or with a proven functional effect. More than 30 SNPs code for amino acid changes, which occur in numerous complex haplotypes and with distinct ethnic frequencies [90]. The most common variant *CYP2B6**6 harbors two amino acid changes Gln172His and Lys262Arg, which occur in various combinations with other changes that are apparently of minor functional significance. The *6 allele occurs with frequencies between 15% and 60% across different populations (Table 9.1), and it is associated with 50–75% decreased hepatic protein expression [71,95,97]. The causal variant for decreased expression was identified as the c.516G>T [Gln172His] polymorphism, which prevents correct splicing of the *CYP2B6* pre-mRNA and leads to a shorter mRNA that lacks exons 4–6 [85]. The second most important functionally deficient allele is *CYP2B6**18 (c.983 C>T [Ile328Thr]), which did not form a functional protein in transfected mammalian cells and may thus be a *null* allele [103]. This allele was not found in Caucasians. In African populations, it occurs with a frequency of up to 7% (Table 9.1). Most other functional polymorphisms occur at lower frequencies [95,103–106]. An allele associated with increased transcription *in vitro* was also identified (*CYP2B6**22, [105]). The –82T>C change was shown to alter the TATA box into a functional CCAAT/enhancer-binding protein binding site that causes increased transcription at an alternative downstream initiation site [105].

The major clinical role of *CYP2B6* polymorphism was elucidated after the *in vitro* studies identified *CYP2B6* as the enzyme responsible for the conversion of efavirenz into its major 8-hydroxylated and 8-, 14-dihydroxylated metabolites [107]. Efavirenz is a potent agent recommended for initial therapy in regimens with two nucleoside reverse transcriptase inhibitors (NRTIs), but patients with subtherapeutic plasma concentrations can develop resistance and treatment failure, whereas those with too high plasma concentrations are at increased risk of CNS side effects. Several clinical studies found that HIV-infected patients homozygous for the 516 T allele develop several-fold higher median AUC values compared to those with only one or no T-allele [108]. The 516 T variant was also associated with increased CNS side effects [109] and treatment discontinuation [110]. In a prospective, genotype-based dose adjustment study, the therapeutic dose of efavirenz could be successfully reduced and CNS-related side effects decreased [111]. Furthermore, it was shown that analysis of rare loss-of-function alleles can improve prediction of high efavirenz plasma levels [106].

CYP2B6 genotype also affects plasma levels of the antiretroviral drug nevirapine [112]. However, the common *CYP2B6* polymorphisms appear to be less penetrant for some other substrates, probably because the amino acid changes can cause additional effects. A single-dose pharmacokinetic study in volunteers revealed no change in total bupropion clearance, although $C_{\max}$, AUC, and metabolic ratio for hydroxybupropion were lower in *6/*6 and *1/*6 compared to *1/*1 [92]. In this study, a higher clearance was found for allele *4, consistent with higher activity of the K262R variant in an *in vitro* system [113]. Cyclophosphamide, one of the most widely used anticancer and immunosuppressant drug, requires bioactivation by P450 enzymes to yield the active 4-hydroxy-metabolite, and *CYP2B6* was shown to be the major enzyme for this step [114]. Studies reported that cyclophosphamide bioactivation may be enhanced by the c.516G>T allele in white subjects, further emphasizing the possibility of substrate-dependent effects of these amino acid variants [115]. *CYP2B6* allele variants were also investigated in the context of the synthetic μ -opioid receptor agonist, methadone,

which is used as a maintenance treatment for opioid addiction, and in $*6/*6$ carriers, (S)-methadone plasma levels were increased, leading to potentially higher risk of severe cardiac arrhythmias and sudden death [116,117].

In conclusion, the clinical impact of *CYP2B6* pharmacogenetics has only recently been investigated. *CYP2B6* genotyping predicts elevated plasma concentrations of efavirenz and nevirapine in HIV-infected individuals. This is in agreement with basic *in vitro* studies showing lower expression as a consequence of erroneous splicing of the most common $*6$ variant. Substrate-dependent effects have to be expected because of the presence of amino acid changes in the polymorphic alleles.

9.3.2.3 Subfamily CYP2C—CYP2C8, CYP2C9, CYP2C18, and CYP2C19.

9.3.2.3.1 Molecular Genetics and Pharmacological Properties. The human *CYP2C* subfamily consists of the four genes *CYP2C18*, *2C19*, *2C9*, and *2C8*, which are localized in this order in a gene cluster on chromosome 10q24. Although *CYP2C18* mRNA is highly expressed in liver, the transcript is not efficiently translated into protein and, therefore, does not make significant contributions to drug metabolism. The other three *CYP2C* members together constitute on average between 30% and 50% of the microsomal hepatic P450 pool, with *CYP2C8* and *CYP2C9* being expressed roughly 10-fold higher than *CYP2C19*. At lower levels, functional *CYP2C* enzymes were also detected [63], for example, in human small intestine, where they are independently regulated, and in cardiovascular tissues [118]. All three expressed *CYP2C* enzymes are inducible by ligands of the PXR/CAR and glucocorticoid (GR) nuclear receptor pathways through different response elements in their upstream regulatory regions [119]. However, the relative inducibilities are different for the three genes. All four *CYP2C* genes are genetically polymorphic. The *CYP2C19* or “S-mephenytoin” polymorphism is one of the early examples of P450 polymorphisms [120]. *CYP2C19* null alleles are common enough among Caucasians and Asians to produce a homozygous PM phenotype. In contrast, the common *CYP2C8* and *CYP2C9* variants code for full-length proteins with amino acid changes that lead to more moderate and substrate-dependent functional changes.

9.3.2.3.2 CYP2C8. *CYP2C8* is mainly responsible for the metabolism of the antidiabetics rosiglitazone and pioglitazone, the antiarrhythmic amiodarone, as well as the retinoic acid drugs used in acne and cancer treatment. Some overlap in substrate specificity with *CYP2C9* occurs, for example, as in the case of ibuprofen [4,121]. Additional important drug oxidations catalyzed primarily by *CYP2C8* are the 6 α -hydroxylation of the natural anticancer drug paclitaxel and the deethylation of the antimalarial amodiaquine, both useful probe drugs for *CYP2C8* phenotyping. In addition to amodiaquine, *CYP2C8* has a major role in metabolizing other antimalarials such as chloroquine and dapsone [122]. The clinical significance of *CYP2C8* became apparent after its involvement in fatal drug interactions was described, which were in part due to its potent inhibition by gemfibrozil acyl-glucuronide, ultimately leading to cerivastatin-induced rhabdomyolysis [123,124]. Many more potent inhibitors at clinically relevant concentrations have been described [125].

Apart from rare variants with no ($*5$, $*7$), reduced ($*8$), or unknown activity, there are three more common alleles *CYP2C8* $*2$, $*3$, and $*4$, which code for amino acid variants (Table 9.1). The $*2$ allele [Ile269Phe] most frequently (15–20%) occurs in individuals of African origin, and much lower to no occurrence is observed in

Caucasians and Asians [126–128]. The heterologously expressed variant had twofold increased intrinsic clearance for paclitaxel because of increased K_m . The *3 allele [Arg139Lys + Lys399Arg] occurs more frequently in white subjects but is almost absent in Africans and Asians. The CYP2C8.3 variant was initially shown to reduce metabolism of arachidonic acid and paclitaxel hydroxylation *in vitro* by ~40% and ~80%, respectively [126]. The evidence for altered pharmacokinetics, toxicity, or efficacy of these drugs in carriers of any of these alleles is however controversial. Owing to the close distance, the CYP2C8*3 variant is in partial linkage disequilibrium to the CYP2C9*2 allele, which may be of particular importance for substrates metabolized by both enzymes such as ibuprofen. Indeed, CYP2C8*3 genotypes were associated, together with CYP2C9*2 and *3 alleles, with reduced clearance of ibuprofen [129]. Some functional effects of CYP2C8*3 are substrate dependent, for example, for repaglinide and rosiglitazone, higher metabolic capacity of this variant was observed. The functionally less-well-investigated *4 allele occurs in Caucasians (~8%) and is practically absent from all other major races. A recent review on CYP2C8 pharmacogenetic studies can be found in Ref. 130.

In conclusion, the most relevant CYP2C8 variants are the alleles CYP2C8*2 and CYP2C8 *3 that code for amino acid variants whose frequencies vary between 7.5% and 20% depending on ethnicity. Their functional effects appear to be substrate dependent.

9.3.2.3.3 CYP2C9. In liver, CYP2C9 is one of the most abundantly expressed P450s. It accepts weakly acidic substances such as the anticoagulant warfarin, the anticonvulsants phenytoin and valproic acid, cardiovascular drugs such as rosuvastatin and losartan, and several nonsteroidal anti-inflammatory drugs (NSAIDs, [131]). Many of these drugs have a narrow therapeutic index, and variations in CYP2C9 activity are thus among the recognized factors for adverse drug reactions. The CYP2C9 enzyme also metabolizes endogenous substances, in particular, arachidonic acid and some steroids, and the fact that it is expressed in endothelial cells implicates it in the regulation of vascular tone [132].

Among the 34 distinct alleles listed on the CYPallele website, the initially discovered alleles, *2 [Arg144Cys] and *3 [Ile359Leu], have been investigated more thoroughly than the more recently identified and less frequent ones. These two variants are present in up to 20% and 15% in Caucasians, respectively, but much less common in Africans and Asians (Table 9.1). According to *in vitro* experiments with expressed mutant enzymes, the CYP2C9.2 and CYP2C9.3 proteins have reduced intrinsic clearance, although the degree of activity reduction appears to depend on the particular substrate. The *2 allele causes reductions in *in vitro* activity of ~20–40%, whereas the *3 allele is more severely affected and its activity reduction can be 70–90% for some substrates. In vivo, this results in clearance reductions of more than 70% in *3 homozygotes and in about half of the clearance for heterozygotes. Other alleles with decreased function but rare occurrence are *5, *6, *8, *11, as well as several promoter variants with unclear significance.

Numerous studies demonstrated the clinical significance of the CYP2C9*2 and *3 polymorphisms for most drug substrates mentioned above. Owing to their common occurrence in Caucasians, there are about 1–2% of homozygous (*2/*2 and *3/*3) and hemizygous (*2/*3) carriers that are at risk to experience more dramatic effects, but even for the heterozygous carriers, higher incidence of adverse drug reactions was

reported. This includes hypoglycemia as a result of treatment with hypoglycemic drugs [133], gastrointestinal bleeding from NSAIDs [134], and serious bleedings from warfarin treatment, where anticoagulant response also depends on variants of vitamin K epoxide reductase. Further examples of the clinical relevance of CYP2C9 polymorphisms can be found in recent reviews [131,135].

9.3.2.3.4 CYP2C19. Compared to CYP2C8 and CYP2C9, the CYP2C19 isozyme has a much lower expression in liver. However, it was the first CYP2C enzyme to be discovered by its marked genetic polymorphism resulting in the *S*-mephenytoin PM and EM phenotypes [120]. The CYP2C19 enzyme was later shown to be the major enzyme for the inactivating metabolism of proton pump inhibitors (PPI), including omeprazole and pantoprazole, and for the metabolic activation of the anticoagulant clopidogrel [136]. CYP2C19 has also a prominent role in the metabolism of several antidepressants of the first and second generation [137].

The PM phenotype results from two null alleles, that is, alleles that are unable to produce any functional protein, whereas EMs carry at least one functional allele. About 3–5% of white and black populations but up to 20% of Asians are CYP2C19 PMs, [6]. The two most common null alleles are *CYP2C19**2, which occurs almost exclusively in Caucasians, and *CYP2C19**3, which occurs primarily in Asians (Table 9.1). A further variant with potential clinical significance is a promoter variant *CYP2C19**17 that appears to be related to increased substrate turnover [138].

The effect of the *CYP2C19* polymorphism on *Helicobacter pylori* eradication therapy is a particularly intriguing example of a clinical application of pharmacogenetics. The common eradication strategy involves application of two antibiotics, for example, amoxicillin and clarithromycin, together with the PPI, which contributes to accelerated ulcer healing and increases effectiveness of the antibiotics. The PPI-induced increase in intragastric pH depends on the *CYP2C19* polymorphism. In several studies in Asia and Europe, it was shown that PM subjects benefit from their lower metabolism rate because their drug levels stay higher for a longer time [139].

Pharmacokinetic effects associated with *CYP2C19* genotype have also been reported for several antidepressants, including clomipramine [140], citalopram [141], and amitriptyline [142]. These were sometimes related to adverse side effects, but an influence on pharmacodynamic outcome remains so far controversial.

Several recent studies investigated *CYP2C19* as a genetic determinant of the efficacy of the platelet-aggregation-inhibiting thienopyridine, clopidogrel (Plavix). This is important in the management of patients with coronary artery disease because a significant proportion of patients may be resistant and may experience insufficient platelet inhibition. The activation of clopidogrel by P450-dependent oxidations has been investigated, and several P450 enzymes, including the CYPs 2B6, 2C9, 2C19, and 3A4, have been found to contribute to the formation of the active 2-oxo metabolite [143]. Numerous clinical studies have confirmed that CYP2C19 PMs have significantly lower anticoagulation effect of clopidogrel, which is associated with an increased risk of major adverse cardiovascular events [144].

In conclusion, the CYP2C subfamily contains three active proteins CYP2C8, CYP2C9, and CYP2C19. Despite the number of common and functionally important variants in each gene being low (one or two), the clinical significance of these polymorphisms has been firmly established for a number of frequently used drugs. Given their strong relatedness in DNA and protein sequence (>82%) and common

mechanisms of transcriptional regulation, it is surprising how unique each enzyme is in terms of substrate specificity and clinical significance.

9.3.2.4 Subfamily CYP2D—CYP2D6.

9.3.2.4.1 Molecular Genetics and Pharmacological Properties. The *CYP2D* locus on chromosome 22q13.1 consists of the functional *CYP2D6* gene and two pseudogenes *CYP2D7* and *CYP2D8P*. While *CYP2D7* is expressed as mRNA in liver, only *CYP2D6* leads to functional protein and constitutes on average about 5% of the total P450 pool. Expression levels vary dramatically from person to person. A recent quantitative comparison of hepatic CYP2D6 protein by Western blot and mass spectrometric analyses revealed comparable results from undetectable in PMs up to 70 pmol/mg of microsomal protein and more in UMs [145]. At the RNA level, CYP2D6 expression is characterized by the occurrence of numerous splice variants. However, with the exception of the effect of polymorphic splice variants (see below), the functional significance of alternative splicing of CYP2D6 pre-mRNA has not been clarified. In fetal liver, CYP2D6 is virtually undetectable, but expression surges within hours after birth [146]. CYP2D6 is also expressed in several extrahepatic tissues, most notably in the gastrointestinal tract and in different areas of the human brain [147–149].

CYP2D6 metabolizes a large number of drugs from virtually all therapeutic classes, including analgesics, antiarrhythmics, antidepressants, antipsychotics, β -blockers, and anticancer drugs. Several highly selective test drugs have been used to determine the CYP2D6 drug oxidation phenotype, including debrisoquine, dextromethorphan, metoprolol, sparteine, and tramadol [150]. Endogenous biotransformations include 5-methoxyindolethylamine *O*-demethylase [151] and regeneration of serotonin from 5-methoxytryptamine [152]. The structure–activity relationships for CYP2D6 substrates and inhibitors were used to develop pharmacophore models [153]. Recently, the crystal structure of the CYP2D6 protein has been resolved, yielding further insights into the active site and the chemical requirements for binding and catalysis [154].

9.3.2.4.2 Genetic Polymorphisms and Pharmacogenetics. Among the human drug-metabolizing CYP1, 2, and 3 families, CYP2D6 shows the greatest impact of genetic polymorphism on expression and function and comparably little influence by environmental and nongenetic factors (except for drug–drug interactions). Initial evidence for *CYP2D6* genetic polymorphism came from population and family pharmacokinetic studies in the 1970s, which showed that deficient debrisoquine 4-hydroxylation [155] and sparteine N-oxidation [156] occur in 5–10% of European Caucasians as a monogenic recessive trait but at much lower frequencies in other ethnicities [157]. The molecular studies that followed have been reviewed in detail previously [6,148,158]. Currently, 78 distinct alleles and a large number of allele variants have been described, and the most relevant ones have been functionally assessed and shown to lead to absent or nonfunctional protein, or to decreased or increased expression (Table 9.1). The most frequent null alleles in Caucasians are haplotype variants of *CYP2D6**4, which all harbor a consensus splice site mutation (1846G>A) that leads to absence of a detectable protein in the liver [159]. Its frequency among Caucasians is about 20–25%, and in white populations, it is responsible for 70–90% of all PMs [160,161]. The low frequency of the PM phenotype in Oriental and African populations is due to the virtual absence of the *4 allele, whereas in African-American populations, it is present with intermediate frequencies. The *CYP2D6* gene deletion allele *5 is present at a

frequency of 3–5% in most populations. The null alleles *3 and *6 are present at frequencies slightly above 1% in Caucasians, whereas the other null alleles are very rare [160,161]. In 10–15% of white individuals, the IM phenotype was shown to be the result of inheritance of the partially defective allele *41 in combination with another partially or fully defective allele. The mechanism involves an intron 6 SNP that leads to erroneous splicing resulting in only a fraction of correctly spliced mRNA [162].

In addition to the SNPs, a large number of structural variations exist at the *CYP2D* locus. Unequal crossing-over between the highly homologous genes involving a certain repetitive sequence also present in the *c-myc* gene leads to variants with deleted, duplicated, or recombined genes. *CYP2D6* gene duplications were identified in combination with various alleles including *1, *2, *4, *6, *10, *17, *29, *35, *41, *43, and *45, but most commonly, it occurs with the functional amino acid variant *2. The overall frequency of the gene duplications in white Europeans is between 1% and 5%, whereas in some Arabian, Eastern African, and Pacific populations, it varies between 10% and over 50%, giving rise to speculations about possible selection processes, which might be related to the striking preference of CYP2D6 for plant alkaloids [158].

While PM alleles are very rare in Africans and Asians, other partially defective alleles termed *17 and *10, respectively, are prevalent. The *17 allele is present at frequencies of up to 30% in Africans [163], and the *10 variant occurs at a frequency of up to 50% in Asians [164]. The partial activity conferred by these alleles leads to a shift in the metabolic drug oxidation capacity toward lower values, which has clinical relevance [165].

The presence of the pseudogenes, structural variants, and numerous SNPs at the *CYP2D* locus requires particular cautiousness in the design of genotyping assays. Coamplification of pseudogenes, unexpected recombination events, and failure to account for important variants, for example, due to ethnic variation, can lead to erroneous interpretation of genotype. Numerous genotyping assays and strategies were developed, which, because of the complexity of variants, usually identify only one functionally dominant key mutation per allele. This possibly reduces the predictive power of genotyping for certain haplotypes. The most comprehensive commercially available platform for CYP2D6 genotyping is the AmpliChip CYP450 test from Roche. This microarray has probes to identify 33 CYP2D6 alleles, including most confirmed variants responsible for absent or impaired enzyme activity and 7 gene duplications, as well as 2 *CYP2C19* variant alleles [166–168].

The *CYP2D6* polymorphism is one of the most intensely studied polymorphisms in man. It has been studied not only in relation to drug response for many CYP2D6 substrates but also as a risk factor for numerous diseases. Most of the epidemiological studies revealed conflicting results, and the reader is referred to specialized articles on the association of polymorphic *CYP2D6* alleles with, for example, Parkinson's disease [169], schizophrenia [170], Alzheimer's disease [171], and several forms of cancer [172–174].

In contrast to the largely inconsistent epidemiological studies, numerous clinical studies have shown profound effects of CYP2D6 polymorphism on pharmacokinetics, therapeutic effect, and associated toxicity of drugs that are either inactivated or activated by this enzyme. The limited scope of this chapter allows to mention only some of the newer studies, for example, on the impact of *CYP2D6* genotype on drug response following treatment with metoprolol [175,176], propafenone and other antiarrhythmics [177,178], and amitriptyline and other antidepressants [142,179–181]. An

important prodrug converted by CYP2D6 to the pharmacologically active substance is codeine, which is O-demethylated to morphine. Increased effectiveness of codeine with sometimes life-threatening opioid intoxication was observed in patients with multiple *CYP2D6* gene copies consistent with higher rates of conversion to morphine in patients with UM phenotype [182–184]. Recently, this scenario has also been the subject of a computerized quantitative modeling study [185].

CYP2D6 pharmacogenetics appears to have a major impact in the adjuvant treatment of breast cancer with tamoxifen, an antiestrogen extensively metabolized in the liver to several primary and secondary metabolites [186]. Formation of at least two metabolites, 4-hydroxytamoxifen and the secondary metabolite endoxifen, thought to be mainly responsible for the antiestrogenic effect because of their high affinity to the estrogen receptor depends mainly on the catalytic action of CYP2D6 [187]. Recent retrospective and prospective studies demonstrated that the CYP2D6 genotype significantly influences the plasma concentrations of these active tamoxifen metabolites, thus influencing treatment outcome [188]. According to these studies, patients with PM or IM phenotype produce lower levels of active metabolites and profit less from the treatment [77]. Nevertheless, it must be realized that the studies so far were limited by size and by the fact that confounding factors have not been taken into account systematically [189–191].

In conclusion, CYP2D6 is one of the cornerstones of pharmacogenetics and its translation into personalized medicine. The clinical significance of the *CYP2D6* polymorphism, which includes variants with completely deficient, decreased, and increased activity, has been firmly established for numerous frequently used drugs.

9.3.2.5 Subfamily CYP2E—CYP2E1. Among the human drug-metabolizing CYPs, CYP2E1 displays a substrate preference for low molecular weight molecules, including ethanol, acetone, pyrazole, acetaminophen, and many other toxicants and carcinogens, and thus is of primary toxicological importance, for example, for the metabolic activation of acetaminophen and many other chemicals [192]. The enzyme is inducible by many of its substrates, and in contrast to the transcriptional induction mechanisms, which play a role for most other drug-metabolizing P450s, CYP2E1 is induced post-translationally by substrate-induced stabilization. A number of studies also established the role of CYP2E1 in oxidative stress and alcoholic liver disease [193,194].

CYP2E1 is the only functional gene of the *CYP2E* subfamily, which is located at chromosome 10q26.3. Relatively few polymorphisms were described compared to other *CYP2* genes [7], but conclusive functional assessment of their phenotypic effects is lacking for most variants, and only moderate associations were described in studies with human liver [195–197]. Association with expression changes was reported for a polymorphic Rsa I site in the 5'-regulatory region of *CYP2E1**5 in one study [196] but not in another [195]. A recent study analyzed 11 polymorphisms and their haplotypes in over 2600 individuals from population samples representing the major geographical regions of the world [198]. As observed in studies on the CYP3A locus (see below), haplotype diversity was much higher in Africa (6–10 common haplotypes) than in other parts of the world (about 1–6 common haplotypes). This study also eluded on the difficulties in relating the haplotypes and alleles with different information content.

Because CYP2E1 is of particular relevance for metabolic activation of procarcinogens and chemical carcinogenesis, numerous pharmacogenetic studies were carried out

toward identifying variants associated with various cancers. As these studies are complex and often contradictory results were obtained, the reader is referred to some recent specialized reviews and meta-analyses on CYP2E1 and the risk of chemically induced cancers [199], its association with lung cancer risk [200], and alcohol-related cancers [201].

9.3.3 Family CYP3

9.3.3.1 Subfamily CYP3A—CYP3A4, CYP3A5, CYP3A7, and CYP3A43.

9.3.3.1.1 Molecular Genetics and Pharmacological Properties. The CYP3A cluster on human chromosome 7q22.1 has a size of 231 kb and comprises the four genes 3A4, 3A5, 3A7, and 3A43. The mouse cluster consists of twice as many genes, but there are no orthologous pairs between mouse and human, suggesting that a single CYP3A gene present in the common ancestor existed, which independently expanded during the last 75 million years [1]. CYP3A enzymes, in particular, CYP3A4, are responsible for the metabolism of ~30–40% of the clinically used drugs from all therapeutic categories. In part, this is explained by the structure of the enzymes. The active site of CYP3A4 is large and flexible enough to bind and metabolize many preferentially lipophilic compounds with comparatively large structures [202]. Typical substrates are, for example, the immunosuppressants cyclosporin A and tacrolimus; macrolide antibiotics, such as erythromycin; anticancer drugs, including taxol, cyclophosphamide, ifosfamide, and tamoxifen; benzodiazepines; the HMG-CoA reductase inhibitors simvastatin and atorvastatin; antidepressants; and opioids [203,204]. CYP3A4 is also an efficient steroid hydroxylase with an important role in the catabolism of several endogenous steroids including testosterone, progesterone, androstenedione, cortisol, and bile acids. The high sequence similarity between the CYP3A isozymes leads to highly similar substrate selectivity, so that no really selective probe substrates could be identified to date. Although several probe drugs that measure general CYP3A activity are available, including midazolam, erythromycin, alprazolam, and dextromethorphan [204], phenotyping for CYP3A is not a trivial task, as results obtained with different probe drugs are not generally well correlated to each other, which is a CYP3A4-specific feature that may be related to allosteric regulation of enzyme activity [205].

In the majority of individuals, CYP3A4 is the most abundantly expressed P450 in liver and intestinal enterocytes, as well as in colon and breast [63,84,206,207]. Expression of the three minor isoforms, CYP3A5, CYP3A7, and CYP3A43, is generally much lower than that of CYP3A4, although their exact contribution to the total CYP3A pool remained controversial [207–211]. CYP3A7 is more abundantly expressed in fetal liver than in adult liver, but the mechanism for this has not been studied in detail [146,212], whereas expression of CYP3A43 is negligible in liver [207]. Different signaling pathways contribute to the complex regulation of the CYP3A genes at the transcriptional level [203]. The xenosensor nuclear receptors PXR and CAR, on binding to structurally diverse drug ligands, including barbiturates, glucocorticoids, and rifampicin, are translocated to the nucleus, where they heterodimerize with RXR and enhance transcription from several PXR and CAR response elements located in the proximal promoter and in the xenobiotic-responsive enhancer module (XREM) region located ~8 kb upstream [213,214]. By contrast, downregulation of CYP3A4 occurs in the course of inflammation [215]. Most CYP3A4 substrates show about 20–50% higher

in vivo clearance in females than males, and this difference has been explained by a higher hepatic expression at the mRNA, protein, and activity levels [216].

9.3.3.1.2 Genetic Polymorphisms and Pharmacogenetics.

CYP3A4. On the basis of a comparison of between- and within-person variances in CYP3A4 catalytic function, Ozdemir *et al.* [217] estimated a high inheritability of CYP3A4 catalytic function that warrants investigation into genetic polymorphism. Nevertheless, it should be noted that expression distribution was found to be unimodal, thus not indicating monogenic control. The CYPallele website currently lists 22 non-synonymous variants, 3 SNPs resulting in frameshift, and a number of noncoding variants. Although several of the amino acid variants were shown to have an impact on catalytic function, their frequency in the general population is low so that homo- or hemizygotes are extremely rare, and therefore, only modest impact on *in vivo* pharmacokinetics can be expected. A more common and frequently studied polymorphism is the proximal promoter variant *CYP3A4*1B* [−392A>G], which occurs in white populations at ~2–9% but at higher frequencies in subjects of African origin (Table 9.1). *CYP3A4*1B* was initially found to be associated with a higher tumor grade and stage in prostate cancer and showed higher nifedipine oxidase activity in human livers [218]. Association of *CYP3A4*1B* with markers of advanced disease was confirmed by some but not all further studies [219,220]. Despite additional *in vitro* studies with different substrates, the functional effect of this variant remained controversial [221–223]. Several systematic resequencing and haplotype tagging studies at the CYP3A locus carried out in ethnically diverse population samples essentially failed to discover any further variants of significant predictive power for CYP3A4 expression and/or function [208,209,220,224–226].

There are several possibilities to explain the apparent discrepancy between the expected high inheritability of CYP3A4 phenotype and the lack of predictive polymorphism in the *CYP3A4* gene. The importance of haplotype structures in the *CYP3A* locus is one possibility, but haplotypes have so far only been considered in few studies [225,227]. In one study, 37 tag SNPs distributed over the entire *CYP3A* locus in 5 ethnic groups were analyzed, and it was concluded that in European Caucasians, the *CYP3A* locus consists of the largest LD (linkage disequilibrium) blocks compared to other ethnic groups and that only 4 haplotypes account for over 80% of common European Caucasian haplotypes [228]. Haplotype diversity may therefore be more important in other ethnic groups, particularly of African origin. It is also possible that some important predictive variants have not been identified yet, as suggested by the recent discovery of an intronic SNP that appears to affect hepatic expression and response to statins [229]. Furthermore, the influence of genetic polymorphism may be masked or influenced by nongenetic effects. Evidence for the latter possibility was provided by an analysis that took the sex-dependent expression of CYP3A4 into account [227]. Finally, the genetic variants that determine CYP3A4 phenotype need not necessarily be located within the *CYP3A* locus. The various regulatory and signaling pathways that influence CYP3A4 expression may harbor variants that modulate constitutive or inducible transcription; for example, in nuclear receptors or their coactivators [230], drug transporters have been suggested to modulate CYP3A4-inducible expression by controlling the intracellular concentration of nuclear receptor ligands [231] and variants of the monooxygenase redox genes NADPH-CYP oxidoreductase and cytochrome *b5* may affect enzymatic activity [232]. Pathway-oriented gene approaches with a broad

coverage of genes in phenotypically well-defined tissues or volunteers may help to advance the pharmacogenomics of CYP3A4.

CYP3A5. In contrast to CYP3A4, expression of CYP3A5 in liver is polymorphic, and only a fraction of about 5–10% of Caucasians but 60% or more of Africans or African-Americans express this minor form. These ethnic differences are largely explained by two alleles that result in aberrant splicing and deficient expression. The most common allele is *CYP3A5*3*, which harbors an intron 3 mutation that leads to aberrant splicing and a truncated protein and occurs in all ethnic groups studied [211]. *CYP3A5*6* with an exon 7 mutation that also leads to an aberrantly spliced mRNA lacking exon 7 was only detected in populations of African origin. The high frequency of the *3A5*3* allele in Caucasians, compared to the lower frequency in Asian and African populations, explains the corresponding opposite frequency pattern of the functional *CYP3A5*1* reference allele that determines expression.

Pharmacogenetic studies addressing the CYP3A5 polymorphism have generally resulted in no or only moderate effects. This lack of penetrance is mainly due to the overlap in substrate selectivity among the CYP3A enzymes and to the minor expression of CYP3A5 compared to CYP3A4. Nevertheless, association with the *CYP3A5* genotype was reported, for example, for the immunosuppressant tacrolimus [233,234], the antihypertensive verapamil [235], and the HIV protease inhibitor saquinavir [236]. Further references on this subject and on the numerous studies on evaluation of CYP3A polymorphisms and cancer risk can be found in specialized reviews [211,237].

CYP3A7. The fetal predominant form CYP3A7 accounts for up to 50% of total P450 content in fetal livers [146,212]. Although expression shifts after birth from CYP3A7 to CYP3A4, it remains polymorphically expressed in some adult livers and in intestine [238]. Most of the CYP3A7 mRNA high expressor phenotypes could be explained by the *CYP3A7*1C* allele, which is more effectively transcribed due to several SNPs in the promoter region that lead to increased binding of and transactivation by PXR/RXR and CAR/RXR heterodimers to a polymorphic ER6 motif also found in the CYP3A4 promoter [238]. Further studies with a specific antibody estimated the relative content of CYP3A7 to the total CYP3A pool to be between 9% and 36% for the ~10% of high expressors and about 10-fold lower in the low expressors [239]. Additional alleles of the *CYP3A7* gene can be found on the CYPallele website [7]. The clinical significance of CYP3A7 polymorphism has not been well studied.

9.4 CONCLUSIONS AND FUTURE PERSPECTIVES

Among the 200 most frequently sold drugs in the United States, about 80% are cleared primarily by CYPs of the CYP1, CYP2, and CYP3 families [4]. The CYP1A2, CYP2C8, and CYP3A4 isoforms, which lack major functional polymorphisms, are responsible for the metabolism of about half of these drugs, whereas metabolism of the other half is by the polymorphic enzymes CYP2B6, CYP2C9, CYP2C19, and CYP2D6, which have an established role in pharmacogenetics [240]. An analysis of adverse drug reaction studies published between 1995 and 2000 identified 27 drugs frequently cited in connection with adverse drug reaction. While 59% of these drugs are metabolized

by at least one polymorphic enzyme, compared to only 7% of randomly selected top-selling drugs, emphasizing the clinical significance of pharmacokinetic polymorphisms [241]. For the major polymorphic human P450s, the most important functional variants have been identified and functionally characterized, although in some ethnically isolated populations, undiscovered important alleles may still exist. Impressive examples of genotype–phenotype or genotype–clinical outcome relationships have been elucidated that suggest advantageous clinical application. The less well predictable genes, especially CYP1A2 and CYP3A4, still pose a big challenge. Future studies need to consider pathways involved in their regulation and concepts for the inclusion of gene–gene and gene–environment interactions, as well as epigenetic aspects. Drug toxicity and treatment outcome depend on many additional genetic and nongenetic factors, and multigene and multifactorial approaches have to be considered more seriously in the future for successful application of the CYP polymorphisms in personalized drug therapy. Integration of such diverse data into comprehensive models of metabolic and gene regulatory networks poses future challenges for pharmacogenetics.

10.1 SUMMARY

The flavin-containing monooxygenase (FMO) is an important human drug-metabolizing enzyme because it oxygenates sulfides and amines, which are two functional groups very prevalent in drugs and drug candidates. FMO also oxygenates many other nucleophile-containing compounds to more polar, readily excreted metabolites. Generally, FMO-mediated metabolism constitutes a detoxication process, but sometimes it produces electrophilic metabolites that inhibit other enzyme systems because FMO is quite recalcitrant to inhibition. FMO is also not readily induced and the properties of lack of inhibition and induction contribute to FMO being a detoxication catalyst. Because FMO is not readily inhibited or induced, most of its functional variability is not due to environmental factors but due to genetic polymorphisms. Compared with cytochrome P450 (P450), drugs and drug candidates that are metabolized by FMO possess less potential for toxicity and adverse drug–drug interactions.

Encyclopedia of Drug Metabolism and Interactions, 6-Volume Set, First Edition.

Highly nucleophilic drugs and drug candidates are oxygenated by FMO, and some of these oxygenated metabolites can be readily retroreduced to the parent compound quite efficiently. Retroreduction of drug candidate metabolites formed by FMO confounds the evaluation of the role of FMO in drug candidates and probably underestimates the amount of metabolism that FMO contributes to new chemical entities. One class of highly nucleophilic agents that are not oxygenated by FMO is the endogenous physiological nucleophiles such as glutathione or cysteine. This likely cytoprotective process probably spares the cell from unnecessary consumption of reductive equivalents of NADPH used in FMO-mediated oxygenation as well as from the loss of thiophile cytoprotective agents such as glutathione.

Introducing a functional group into drug candidates that are metabolized by FMO may be beneficial in drug development. This might distribute the metabolism of the drug candidate over a wider set of enzymes as well as potentially provide FMO metabolites that are generally polar, nontoxic, and readily excreted. By avoiding metabolism (and bioactivation) by P450, the prospects for increasing druglike properties of a drug candidate are likely increased. Because so many drugs are metabolized by P450 3A4, decreasing the amount of metabolism through this enzyme system is likely to decrease adverse drug–drug interactions. Distributing the metabolism of drugs over a wide range of metabolic processes including FMO might decrease reliance on one metabolic pathway and decrease toxicity and adverse drug–drug interactions.

10.2 INTRODUCTION

The FMO (E.C.1.14.12.8) is a microsomal, NADPH-dependent, chemical- and drug-metabolizing enzyme that possesses broad substrate specificity [1,2]. Compared to biosynthetic enzymes with great substrate specificity, monooxygenases such as FMO appear to trade robust rates of metabolism for the ability to accept a wide variety of nucleophilic heteroatom-containing chemicals and endogenous materials [3,4]. In this regard, FMO resembles P450, although its specific rates of metabolism appear to be greater than those of P450. Generally, FMO converts lipophilic nucleophilic compounds to more polar metabolites that are more readily excreted; for example, tertiary amines are converted to their *N*-oxides, and often, the *N*-oxides possess significantly less pharmacological activity. FMO can bioactivate compounds to more reactive metabolites; however, these reactive products generally leave the product domain of FMO but can inactivate other proteins (including hemoproteins such as P450). This aspect of FMO function underscores an underlying mechanism: somehow the product-binding domain of the enzyme precludes some very reactive metabolites from inactivation of the enzyme. Amino acid residues surrounding the product-binding domain presumably are non-nucleophilic and prevent covalent binding by electrophilic metabolites. Accordingly, FMO is not easily inhibited. Lack of ready inhibition of FMO is in contrast to the relatively easily inhibited P450 class of enzymes and could suggest that FMO would have less adverse drug–drug interactions via FMO-dependent metabolism [5].

There are five forms of FMO (i.e., FMO1–5) that show 50–58% amino acid identity across species lines [1]. Additional pseudogenes (i.e., FMO6–11) have been reported in human tissue [6,7]. Because FMO pseudogene products (i.e., FMO6–11) lack functional activity, they are not discussed further in this summary. FMO utilizes a

peroxyflavin cofactor as the source of molecular oxygen, and for human FMOs, much of the FMO metabolism literature published to date suggests FMO3 as having a prominent role in FMO-dependent drug and chemical metabolism [8]. It should be pointed out, however, that FMO5 is the most prevalent form of FMO in adult human liver but its functional role is not clear, possibly because of the limited number of substrates reported [3,9]. In contrast to many small animal models of hepatic FMO where FMO1 is often a prominent hepatic form in adult human liver, very little FMO1, FMO2, and FMO4 are present [3,10]. Relatively few reports in the literature related to human FMO-mediated metabolism exist, and this is surprising in view of the fact that FMO3 is present in adult human liver to a surprisingly great extent. For a normal liver, FMO3 is present in ~65% of the amount of protein that is typically observed for P450 3A4 [10]. Adult human liver FMO3 is a prominent enzyme that likely plays a larger role in the metabolism of chemicals and drugs than has previously been reported. There are several possible reasons for this. First, FMO is thermally labile and the order of addition of cofactor (i.e., NADPH) is very important to preserve maximum enzyme activity. As much as 80% of FMO activity can be lost by treating microsomal or other sources of FMO3 with heat (even preincubation at 37°C) for as little as one minute preincubation in the absence of NADPH [11]. Accordingly, incubations initiated by the addition of NADPH to prewarmed preparations of microsomes or FMO considerably decrease the functional activity. Traditionally, initiation of microsomal incubations by the addition of NADPH has been done to decrease autooxidation of N- and S-containing substrates that are particularly prone to autooxidation. However, autooxidation of susceptible substrates can be precluded by addition of an antioxidant such as diethylaminepentacetic acid (DETAPAC). Addition of substrate to a chilled incubation containing a source of FMO, NADPH, and an antioxidant and initiation of the incubation at 37°C is an optimal means of preserving FMO functional activity. Second, the nature of the metabolite formed by FMO (i.e., *N*-oxides, *S*-oxides, and hydroxylamines) is sometimes difficult to quantify from an analytical standpoint. In addition (and this point is discussed in greater detail below), metabolites of FMO can undergo retroreduction and reform the parent drug or chemical. Thus, no apparent FMO-dependent metabolism is present when in fact, considerable metabolites are formed, but they are rapidly retroreduced. Another aspect is that sometimes, initially formed FMO-dependent metabolites (e.g., hydroxylamines) are more nucleophilic than the starting amine and are more extensively metabolized than the parent amine. Moreover, the ultimate metabolite may not be readily recognized as arising from the starting material. In rare cases, the metabolite (e.g., a tertiary amine *N*-oxide or an *S*-oxide) may be chemically unstable and may undergo a Cope-type elimination to provide a product that is also not readily recognizable as derived from a typical FMO-mediated transformation. In fact, sometimes, FMO-dependent metabolites resemble those that might arise from P450. Finally, the efficiency of FMO-mediated oxygenation is also highly dependent on the quality of the microsomes or other source of FMO. Compared to P450, for example, there are some significant differences to the approach to preparing microsomes highly enriched with FMO functional activity, but most approaches involve assuring that the microsome sample is kept at 4°C or less during preparation [11]. To further illustrate ways to characterize FMO and distinguish functional enzyme activity from P450, a few simple methodological approaches are listed below that can be used to distinguish FMO-dependent from P450 dependent metabolic processes [12].

While the dogma that FMO oxygenates highly nucleophilic compounds has been described above, there are a number of important exceptions to the rule. For example, some unusual examples of FMO-mediated carbon-centered oxygenation (e.g., 6-methylhydroxylation of the anticancer agent 5,6-dimethylxanthenone-4-acetic acid [13] and carbon oxygenation and defluorination of 4-fluoro-*N*-methylaniline [14]) have appeared in the literature. The latter example is particularly intriguing because FMO1-mediated carbon oxygenation of 4-fluoro-*N*-methylaniline is coupled with defluorination to afford 4-*N*-methylaminophenol via an electrophilic quinoneimine intermediate. Another important class of nucleophiles not oxygenated by FMO includes biological nucleophiles (e.g., cysteine or glutathione). Examined from the standpoint of biology, FMO presumably does not accept cysteine or glutathione because S-oxygenation of such nucleophiles would rapidly deplete cysteine or glutathione, putting defense mechanisms of the cell at risk. S-Oxygenation of biological thiols would also deplete NADPH, and this would be biologically wasteful and also put the cell at risk from biological electrophiles because of the inability of NADPH to otherwise participate in endogenous cellular defense mechanisms. Apparently, key amino acids in the mouth of the FMO substrate-binding channel are specifically in place to ward off biological nucleophiles. The fact that FMO is not prone to inhibition by electrophilic oxygenated metabolites (e.g., even highly reactive sulfenic acids) suggests that FMO may have evolved to detoxicate lipophilic nucleophilic N- and S-containing compounds in the primordial biota. Inhibition of FMO would have brought this vital function to a halt and predisposed any developing biology to risk. Likewise, FMO apparently evolved critical amino acids in the substrate-binding channel to disavow the metabolism of cellular protective agents (e.g., glutathione oxidized to glutathione disulfide). By using both these mechanisms, FMO presumably provides a strong detoxication presence to the cell. It is not clear that this is the physiological role of FMO, although, to date, the physiological role of FMO has eluded identification [2,15,16]. Certain physiologically important N-containing compounds are also efficiently N-oxygenated. For example, the neurotransmitters tyramine and phenethylamine are sequentially N-oxygenated by FMO3 to the oxime [17,18]. N-Oxygenation of these and other biologically relevant amines may serve as a detoxication pathway to decrease the accumulation of excess and deleterious amines by converting them into metabolites that possess considerably less pharmacological activity than the parent amine [19].

The prediction is that FMO will oxygenate any nucleophilic heteroatom-containing compound that can be oxidized by hydrogen peroxide or peracids [20]. This is one distinction for this class of monooxygenase made on the basis of products derived from FMO: compared to P450, the structures of products are relatively easy to predict with a great deal of certainty. However, FMO does not appear to oxygenate biological nucleophiles (e.g., glutathione and cysteine), although there are some apparent exceptions (e.g., biotin [2]).

This chapter summarizes some of the general considerations of the role of FMO in preclinical drug lead selection and development. The idea that concepts of FMO drug metabolism can be used effectively to guide preclinical drug lead development is not new. Previously, some of these ideas were summarized [5]. Now, a few examples are emerging that underscore the importance of FMO3 in human drug development. The idea is that building drug lead design strategies for a wider range of metabolic pathways of a molecule to decrease reliance (or dominance) on any one metabolic pathway (e.g., P450 3A4) could have significant advantages. Engineering soft nucleophilic centers

into molecules could afford a greater amount of metabolism to go through the FMO3 detoxication route. This may improve detrimental metabolism, toxicity, and bioavailability issues that sometimes beset drug candidates and result in failure of candidates to advance to clinical drug status. Because FMO3 is not readily inhibited or induced, drug candidates that are metabolized by FMO3 may offer advantages by way of decreasing adverse drug–drug interactions that have been observed for drugs prominently metabolized by metabolic enzymes that are readily induced or inhibited. This is not to say that rapid metabolism should be built into a drug candidate. On the contrary, as we shall see with a number of examples, it is likely that FMO3-related metabolism also enables futile metabolic cycles of oxygenation and retroreduction (e.g., for *N*-oxides and *S*-oxides), thus enabling potentially greater cellular accumulation of the parent drug, greater therapeutic efficacy, and more favorable bioavailability. It is possible that the overall process of FMO3-mediated oxygenation and consequent retroreduction are a much greater dynamic than previously recognized. Of course, in addition to FMO-mediated processes, there are many other metabolic processes that can contribute to the overall biotransformation and distribution of a drug candidate. In this chapter, a summary of some of the differences between FMO and other metabolic processes is provided. To stimulate further discussion, the author takes the position that judicious use of soft nucleophiles incorporated into lead candidates and incorporation of FMO-dependent metabolism into drug design paradigms may be useful to improve the overall drugability of candidates and may decrease potential adverse drug–drug interactions.

10.3 OVERVIEW OF THE DRUG DISCOVERY PROCESS

The drug discovery process has changed dramatically over the past 20 years [21]. The drug discovery pipeline has expanded with the use of combinatorial chemistry, rapid synthetic methods, and high throughput screening. However, the success rate of moving a new chemical entity (NCE) forward to an approved drug status is low and the expense is considerable [22]. In the 1960s and 1970s, the observation that many drug candidate failures in clinical development was due to inappropriate pharmacokinetics ushered in a new approach that incorporated a greater reliance on ADMET (absorption, distribution, metabolism, excretion, and toxicity) properties earlier in the preclinical setting [23]. Drug metabolism and pharmacokinetic studies in small animals planned and carried out earlier in the preclinical drug development paradigm and used to make predictions about the way drug candidates could be metabolized and distributed in humans have become a more accepted strategy. While predictions about the way small molecules are handled in small animals compared to humans is an inexact science, utilization of ADMET studies early in the drug development pipeline has decreased the failure rate due to inappropriate pharmacokinetic properties [22,24]. The reported success rate for drug candidates that entered clinical trials was reported as improved for the period between 1981 and 1992 because of improved pharmacokinetic properties and a greater understanding of chemical toxicology [25,26]. This may have had something to do with the improved practice of high throughput synthesis and screening coupled with *in vitro* ADMET studies that improved the metabolic properties and bioavailability for preclinical drug development during this period. However, the success rate reported for this period (i.e., 20.9%) is still unacceptably low and more recent data do not point to

an improvement [27]. The high attrition rate for drug development that still persists is likely due to unfavorable toxicologic properties of new drug candidates. Less progress has been made in understanding the fundamental chemical and biological basis underlying the reason that certain compounds cause toxicity. Compounding the problem is the uncertain nature that small animal studies extrapolate to the human situation [28]. While there is general agreement that production of metabolic reactive metabolites and intermediates is linked to impairment of cell function and cell death, it is not completely clear how small animal toxicology studies relate to human toxicology other than to follow the general idea that it is prudent to divert metabolism pathways from those that produce reactive electrophilic metabolites [29]. Metabolic bioactivation of small molecules to toxic materials as an underlying principle responsible for toxicity is not a new concept, and the idea of linking protein and DNA covalent modification with drug toxicity in *in vitro* and *in vivo* systems is becoming more and more widely accepted. New molecular and genetic approaches have emerged to identify the potential for metabolic bioactivation. Today, many departments responsible for drug safety and ADMET in the pharmaceutical industry have established protocols to identify potentially problematic compounds by a process including (i) reaction phenotyping (to identify the prominent enzymes involved in the metabolism of the drug candidate), (ii) induction or inhibition of P450 (the enzyme system that accounts for about 65% of human drug metabolism), (iii) covalent binding studies (that indicate if reactive electrophiles are being created *in vitro* or *in vivo*), and (iv) pharmacogenetic studies that point to a metabolic potential for adverse drug–drug interactions. With this information in hand, a more complete understanding of the potential for drug toxicity and adverse drug–drug interactions of a drug candidate can be assessed. However, it is likely the situation is much more complex because the biology and molecular genetics are more complex than we currently understand. To underscore this point, paradoxically, drugs of significant clinical utility that possess undesirable properties (e.g., covalently modify proteins or induce or inhibit P450) are still on the market. It is possible that the delicate and complex balance between drug candidate metabolic bioactivation and detoxication is at play under this situation in ways that we still do not fully appreciate.

While the use of combinatorial chemistry and large library screening for identifying “hits” of a pharmaceutical target in the early stages of a drug screening campaign has led to an increase in the number of compounds evaluated, many times the “hits” are of low quality from the standpoint of pharmaceutical properties (i.e., solubility, permeability, bioavailability, and chemical and metabolic stability). A key aspect of drug development is to identify compounds with ADMET and physiochemical property deficiencies as early as possible in the drug development pipeline to advance the candidates possessing the properties leading to the greatest likelihood of success. Two key developments that have spurred advances in the area of ADMET and physiochemical or pharmacokinetic properties have been in the area of genetics (e.g., genotyping to decrease idiosyncrasies) and advances in bioanalytical chemistry (e.g., LC-MS/MS to detect and quantify metabolites), respectively. However, even extensive knowledge of the enzymes involved and the types and quantities of metabolites formed do not completely address deficiencies in understanding their role in toxicity. In addition to the parent drug, the issue of the role of metabolites in the toxicity of drug candidates has emerged in the discussion to explain possible adverse drug-induced toxicities [30]. Generally, the type of metabolite under consideration is a stable drug metabolite that

can be isolated or synthesized as opposed to chemically reactive metabolites or short-lived metabolites that cannot be readily isolated or synthesized. Part of the challenge to characterize the relevance of a metabolite stems from the question as to the level of metabolite formed (i.e., should the metabolite studied be formed at a level of 5%, 10%, or 20% or more of the parent?) and how much effort should be invested in evaluating the toxicity of the metabolite and which metabolites should be studied (i.e., should just human drug metabolites or both small animal and human drug metabolites be studied?) [31]. Nevertheless, for drug approval in the United States, it is likely that increased evaluation of human drug metabolites that are also particularly prevalent in small animals administered the parent drug will be required by the US Food and Drug Administration [32]. Thus, synthesis, characterization, and quantification of drug metabolites will take on an even larger role in drug development and safety evaluation in the future. Because often metabolite synthesis is a nontrivial undertaking, in the future, it may be that use of enzyme-based or semisynthetic approaches will play a larger role in producing difficult-to-obtain metabolites.

Improving the ADMET properties earlier in the drug development paradigm will continue to play a prominent role in preclinical drug discovery. It has been suggested that medicinal chemists would prefer to work in a lead compound series that possesses tractable pharmaceutical and physiochemical properties with lower potency than the other way around [33]. Said in another way, it is more difficult to reengineer or rescue a compound with inherently poor pharmaceutical, chemical, or ADMET properties than to start with a series that possesses good druglike properties and work to improve potency [34]. Another way to express this idea is by the concept of identifying candidates with undesirable properties early in the discovery process and discarding those candidates for the ones with more favorable ADMET and physiochemical properties [35]. Thus, greater resources can be expended on drug candidates with favorable properties and considerably less time and money on candidates with poor prognosis for success. Today, considerable progress has been made to attempt to explain the mechanistic basis for metabolism in the toxicity of drugs and carcinogens. Most of the effort has been directed at P450, and this is understandable in view of the large percentage of chemicals that are prominently metabolized by P450. However, the information is not complete and is lacking in non-P450 drug-metabolizing enzymes such as FMO. A more thorough knowledge of FMO- and other non-CYP-mediated metabolism could provide additional understanding concerning predictions about metabolism, toxicity, and human drug development [36]. Accordingly, this chapter summarizes recent advances related to FMO and drug development with the hope that some of the information will be useful to solve problems and develop new approaches in the use of drug metabolism in drug development.

10.4 ACADEMIC DRUG DEVELOPMENT USING ADMET

With the advent of the NIH Roadmap and funding of university and research institute high throughput molecular probe discovery (<http://pubchem.ncbi.nlm.nih.gov/>), considerably greater attention has been focused on probe and drug discovery in the nonprofit setting. However, in academia, application of ADMET concepts early in the probe or medications development approach has not been as widely utilized. The author suspects that as more and more academic laboratories begin to work on probe and

drug discovery and drug repurposing (i.e., drug rescue to improve a known drug that possesses a weakness or the improvement of a clinical candidate that needs removal of a deficiency to become a drug), application of ADMET concepts early in the drug discovery paradigm may come into vogue and result in more druglike materials from the academic setting. Out of economic necessity and because of the expense of large chemical libraries, the Human BioMolecular Research Institute (HBRI) has embraced using concepts of dynamic medicinal chemistry in its molecular probe and medications development programs [37]. This is because typical academic laboratories including HBRI do not have the financial or other resources for extremely large-scale library screening and pharmacological compound evaluation throughput that a typical for-profit entity has at its disposal. Dynamic medicinal chemistry is an iterative process of recursive chemical synthesis, testing, and optimization by utilizing ADMET principles early in the discovery phase to focus on relatively modest-sized “smart libraries” of druglike compounds that have a much greater chance of surviving and possessing suitable properties for *in vivo* efficacy testing. At HBRI, progress has been made turning high throughput screening “hits” into drug leads with a very modest budget [38,39]. Synthesizing “smart libraries” of druglike materials early in the preclinical drug development paradigm could in principle lead to more favorable candidates with fewer liabilities. The goal of this approach is not to predict the toxicity of a series of compounds but rather to avoid compounds that could afford toxicity and develop more promising candidates in the first place. Such candidates would be more likely to be useful in preclinical animal model efficacy studies because they are designed on the basis of ADMET properties to possess appropriate pharmacophores that are associated with greater bioavailability and other favorable pharmaceutical properties. To illustrate this point, an example from one of our in-house NIH Roadmap Projects is considered. Figure 10.1 shows the structure of a potent nuclear factor-kappa B (NF- κ B) inhibitor.

NF- κ B is a member of the family of transcription factors that play a critical role in many pathways including host defense, immune responses, inflammation, and cancer. The NF- κ B pathway activated by antigen receptors is critical for acquired (as opposed to innate) immunity and contributes to T- and B-lymphocyte activation, proliferation, survival, and effector functions. Dysregulated NF- κ B activation in lymphocytes can contribute to the development of autoimmunity, chronic inflammation, and lymphoid malignancy [40,41]. The NF- κ B activation pathway linked to antigen receptors involves a cascade of adapter and signal-transducing proteins, which minimally includes Carma1, Bcl-10, Paracaspase (MALT1), TRAF6, and Ubc13. In T and B cells, the NF- κ B pathway is initiated by protein kinase C (PKC)- θ and PKC- β , respectively, that induces phosphorylation of components of this signaling pathway,

Figure 10.1 Structure of NF- κ B inhibitor **1** and analogs **2** and **3**.

leading ultimately to inhibitor of $\kappa\beta$ Kinases (IKKs) activation through a mechanism involving IKK- γ [42]. Dysregulated antigen-receptor-mediated NF- κ B activation can contribute to the development of autoimmunity, chronic inflammation, and malignancy. A chemical biologic screening strategy for identification of chemical compounds that selectively inhibit antigen-receptor-mediated NF- κ B activation was devised and implemented [39]. Chemical libraries comprising a total of 110,000 compounds (http://mlsmr.glpig.com/MLSMR_HomePage/) were screened for inhibitors of antigen-receptor-mediated NF- κ B activation. Compounds with an $IC_{50} < 3 \mu M$ were further characterized by 12 additional counter-screens that helped determine inhibition selectivity. From the initial screens, three hits with IC_{50} values $< 2 \mu M$ were identified and confirmed as selective for the antigen receptor activation pathway by the counter-screen assays. Of the three hits, benzimidazole (**1**) (Fig. 10.1) was found to be a highly potent and selective inhibitor of antigen-receptor-mediated NF- κ B activation.

Because the next goal was to test the NF- κ B inhibitor *in vivo*, and because a few sites of **1** could be prone to metabolism and decrease *in vivo* potency, we examined **1** and a few analogs for metabolic stability. As is standard in our dynamic medicinal chemistry approach, *in vitro* metabolic stability studies in the presence of both human liver microsomes (HLMs) and S9 and a reduced NADPH generating system was done with compounds **1**, **2**, and **3**.

In vitro metabolic stability studies showed compounds **1–3** were quite stable to hepatic metabolism. Generally, if a compound has a half-life of > 60 min in these types of *in vitro* metabolism studies, it is judged sufficiently stable to move the compound into *in vivo* studies. Of course, if Phase II conjugation metabolites could be formed, addition of the appropriate cofactor is necessary to observe optimal phase II metabolism. Another possible explanation for metabolic stability of **1–3** was that **1**, **2**, or **3** inhibited its own metabolism. This was a distinct possibility because imidazole-containing compounds are known to inhibit P450. However, significant inhibition of P450 3A4-mediated microsomal hydroxylation of testosterone by **1**, **2**, or **3** was not observed [38], suggesting that inhibition of its own metabolism was not occurring. However, it is possible that some of the metabolic stability of compounds **1–3** was due at least in part to inhibition of other P450s that are more prominent in the metabolism of **1–3**.

That metabolic deficiencies do not appear to be present in **1–3** have thus encouraged more extensive biological studies of these compounds [39]. Metabolic liabilities have significantly contributed to the failure rate of NCEs as clinical candidates and because P450-mediated bioactivation has been associated with P450 inhibition and induction (two features that can confound clinical candidate advancement), improving the metabolism by distributing the metabolism of a drug candidate over a wider range of metabolic enzymes may have significant advantages. As described above for the NF- κ B inhibitor **1**, during lead evaluation and optimization, several steps were taken to improve the druglike properties of **1**, including testing for metabolic stability and inhibition of P450. Appropriate ADMET properties for **1** have afforded a compound that can be tested for efficacy *in vivo* and can possibly lead to a candidate with a favorable bioavailability profile. Even in an academic setting, employing concepts in drug metabolism and applying informed approaches for acceptable physiochemical drug properties can lead to elaborating more druglike materials with decreased potential for adverse drug–drug interactions. This can ultimately lead to biological probes or drug candidates with more favorable properties and to increased success rate for clinical candidates.

10.5 ENHANCING DRUG CANDIDATE SELECTION

Because many examples of drugs with adverse drug–drug interactions have been reported for drugs that are prominently metabolized by one enzyme system (e.g., P450 3A4), one potential strategy to avoid this situation is to distribute the metabolism of a drug over a wide variety of monooxygenases including FMO. In principle, this could also lead to a decrease in potential toxicity, if toxicity was related to one major metabolite. One of the purposes of this chapter is to point out examples where optimization of the role of FMO in drug metabolism and drug design could lead to advantages in drug development owing to decreased toxicity and decreased adverse drug–drug interactions. One recent example comes from the development of a multitargeted Src kinase inhibitor called TG100435 by TarGen, Inc., (San Diego, CA). Src is dysregulated in several types of cancers and is involved in tumor progression and metastases [43]. Anticancer activity was observed in the parent drug, TG100435, **4**, and its tertiary amine *N*-oxide metabolite, **5** (Fig. 10.2).

The tertiary amine *N*-oxide metabolite was formed by FMO in preclinical species including human, dog, rat, and mouse liver. FMO-mediated formation of tertiary amine *N*-oxides is not that unusual, but it is unusual that the *N*-oxide possessed potent anti-cancer potency. Generally, polar, readily excreted *N*- or *S*-oxide metabolites arising from the action of FMO possess less biological activity than the parent compound. This is because *N*- or *S*-oxides, being polar metabolites, tend to part away from lipophilic centers that are often associated with molecular drug targets. However, *N*- or *S*-oxides can be retroreduced to their parent compounds, and this complicates matters somewhat insofar as determining which compound is the active species. In the

Figure 10.2 Chemical structure of the Src kinase inhibitor, TG100435 (compound **4**), and its tertiary amine *N*-oxide, TG100855 (compound **5**).

case of TG100435, *N*-oxygenation and *N*-oxide retroreduction plays a large part in its metabolism. FMO, and not P450, is apparently reported to be solely responsible for formation of the *N*-oxide, TG100855, although P450 3A4 contributed to other parent compound metabolism [44]. This conclusion was based on studies using some of the standard methods currently used to distinguish FMO from P450-mediated metabolism, including (i) use of microsome preparations enriched in P450 and/or FMO, (ii) incubation with selective inhibitors of P450 or alternate competitive substrate inhibitors of FMO, (iii) thermal inactivation studies in the presence or absence of NADPH under conditions that largely abrogate FMO activity and retain P450 functional activity, and (iv) use of highly purified recombinant P450 and FMOs [12]. That the *N*-oxide TG100855 was observed as a prominent metabolite followed from investigations of the kinetics of *N*-oxygenation versus *N*-oxide retroreduction back to the parent amine. In microsomes, *N*-oxide retroreduction was 15-fold slower than FMO-mediated *N*-oxygenation.

To examine the metabolic retroreduction of TG100855, compound **5**, to its parent, (i.e., TG100435, compound **4**), several approaches were tried. The experimental approaches included (i) synthesizing the authentic *N*-oxide metabolite and incubating it with liver microsomes in the presence or absence of NADPH, (ii) incubating the *N*-oxide in heat-inactivated liver microsomes to show that FMO was not responsible for *N*-oxide retroreduction, (iii) incubating the *N*-oxide in the presence of recombinant P450 with or without P450 inhibitors to show that P450 was not responsible for *N*-oxide retroreduction (in fact, the P450 inhibitor 1-aminobenzotriazole (ABT) actually increased retroreduction from three- to fourfold), and (iv) varying the amount of P450 reductase present in the microsomal and P450 incubations, showing that retroreduction was tracked with the P450 reductase amount (although recombinant P450 reductase in phosphate buffer alone did not cause retroreduction of **5** to **4**). Because P450 reductase alone did not retroreduce **5** to **4**, additional factors, presumably involving other cofactors or microsomal or lipidoidal factors, are involved in retroreduction of **5**. In addition, the results did not indicate whether other enzymes associated with retroreduction (i.e., aldehyde oxidase, quinone reductase, or other hemoproteins) contribute to *N*-oxide retroreduction of **5** [44]. Regardless, this is the example of a futile metabolic cycle involving retroreduction of an FMO metabolite that may be very useful from a clinical standpoint.

10.6 FMO IN DRUG CANDIDATE SELECTION

To date and to the author's knowledge, there have been no published reports specifically utilizing FMO in a drug candidate selection process. However, there have been several drugs that have been recognized as having FMO as a prominent contributor to their metabolic profile and more often than not, this has resulted in a useful outcome or at least an advantage from the standpoint of more favorable metabolism or decreased adverse drug–drug interactions. Utilizing functional groups in drug development candidates that are metabolized by FMO may have some advantages compared to a molecule predominantly metabolized by P450 (and, in particular, P450 3A4). This is because in contrast to P450, FMO is not readily inhibited or induced. Accordingly, drug candidates that avoid prominent P450 metabolism may possess more attractive pharmacokinetics and have a better safety profile. Generally, FMO is not readily inactivated but can undergo alternate substrate competitive inhibition by chemicals that

contain functional groups with low K_m values and are readily oxygenated by FMO (i.e., thiones, thioureas, thioamides, and thiols), but these functional groups are not commonly present in drugs. True competitive inhibition of FMO is rare. In contrast to P450, no reports of a time-dependent irreversible inactivator of FMO have appeared in the literature. In rare cases, apparent FMO inhibition is actually the result of interference with the NADPH cofactor-binding site. One example of this is inhibition of FMO by indomethacin [45]. For nitrogen-containing functional groups that are widely present in drugs, frequent alternate substrate competitive inhibition is not observed probably because the commonly present nitrogen-containing functional groups in drugs (i.e., tertiary and secondary amines) generally do not possess K_m values that are low enough for FMO, which would afford apparent inhibition. In contrast to P450, the lack of apparent inhibition of FMO may contribute to decreased adverse drug–drug interactions for drugs prominently metabolized by FMO because a detoxication role of FMO is unaffected.

A few reports of FMO induction by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin treatment have been noted in mice [46,47]. In addition, in experimental small animal models of diabetes, significant increases in FMO have been observed [8], and in one study, elevated levels of FMO were restored to normal after treatment with insulin in the diabetic rat [48]. In another study, significant downregulation of FMO was observed in different mouse models of inflammation [49]. However, the general lack of extensive examples of induction of FMO also suggests that compared with inducible forms of P450, adverse drug–drug interactions will also be less for drugs mainly metabolized by FMO. Because human FMO is not readily induced or inhibited, it is likely that most of the variation in metabolism due to human FMO is not dependent on environmental factors but on genetic polymorphisms. Because the pharmacogenetic basis for FMO variability has been described in recent reviews [8,50], it is not discussed further in this summary, except to highlight some of the functional consequences of drug metabolism.

There are several examples of currently used drugs that are extensively metabolized by FMO and show significant differences in efficacy or bioavailability apparently due to FMO genetic polymorphisms. For example, the prodrug sulfoxide (sulindac) is retroreduced to sulindac sulfide, which is an anti-inflammatory agent and sulfide substrate of FMO [51]. Retro-S-oxygenation of sulindac sulfide decreases the efficacy of the anti-inflammatory agent in familial adenomatous polyposis (FAP) [52]. Individuals with a genetic polymorphism of FMO3 have a defective ability to convert the active sulfide to the inactive *S*-oxide prodrug, resulting in greater concentrations of the active agent. Those individuals with FMO3 genetic polymorphisms show greater efficacy in the treatment of FAP [53].

Two examples of an FMO3 genetic polymorphism that decreases metabolism and increases the efficacy of drug administration stem from the N-oxygenation of ranitidine [54] and the antiulcer agent and benzydamine [55]. Tamoxifen is an example of a tertiary amine substrate of FMO3 that shows an interesting relationship between tissue-selective metabolism and toxicity [56]. In the adult human liver, where P450 is primarily responsible for tamoxifen hydroxylation, a sulfate metabolite that is produced covalently labels hepatic DNA and produces cellular toxicity. Because FMO1 preferentially N-oxygenates tamoxifen and is present in the kidney but not in the adult liver, detoxication by FMO1 protects the renal tissue from covalent binding of tamoxifen metabolites. The lack of FMO1 in the adult human liver predisposes the adult liver to P450-mediated bioactivation and covalent binding.

Itopride is another example of a second-generation drug that was reengineered to decrease a deficiency and optimize its drug efficacy [57]. Itopride is a gastrokinetic agent that is related to mosapride. In contrast to mosapride that is predominantly metabolized by P450 3A4, itopride is primarily converted to the tertiary amine *N*-oxide by FMO3. Because itopride is not metabolized by P450 3A4, it does not engage in adverse drug–drug interactions that have been described for mosapride [58].

Finally, a considerable number of reports have shown a relationship between FMO3 genetic polymorphisms and defective trimethylamine *N*-oxygenation [59–61]. Conversion of trimethylamine (TMA) to its *N*-oxide is a detoxication and deodoration process resulting in the formation of a polar, readily excreted metabolite. For certain individuals with causative FMO3 mutations, trimethylamine is not *N*-oxygenated and accumulates and causes the individual to possess an offensive odor. It is notable that no apparent retroreduction of trimethylamine *N*-oxide occurs. This may have been an important evolutionary advantage to increase the clearance of trimethylamine from the body. What is more likely is that the various reductases that retroreduce tertiary amine *N*-oxides to the tertiary amine do not accept a polar material such as trimethylamine *N*-oxide (TMA *N*-oxide). Regardless, defective TMA metabolism has provided a keen insight into the functional aspects of FMO because the naturally occurring genetic mutations have shed light on amino acids in FMO3, which are critical for function.

10.7 FMO-MEDIATED METABOLISM: STRONG NUCLEOPHILES

10.7.1 Thiones

Electron-rich highly polarizable nucleophilic functional groups are generally accepted as substrates for FMO [62]. Barring steric effects that limit approach to the substrate-binding domain of FMO, highly nucleophilic thiones, thioamides, thioureas, thiocarbamides, thiocarbamates, and the like are the substrates most efficiently *S*-oxygenated by FMO. The same is also likely for nucleophilic phosphorus- and selenium-atom-containing counterparts, but this has not been exhaustively examined. This substrate selectivity can be most easily understood in terms of FMO-accepting lipophilic highly polarizable nucleophilic compounds as substrates. A distinction between endogenous substrates and dietary substrates should be made for both *N*- and *S*-containing compounds metabolized by FMO. As described previously [2], an endogenous substrate (e.g., tyramine) or a substrate that results from a conjugate (e.g., cysteine conjugate) is synthesized in the body. Dietary constituents (e.g., alkaloids or plant-derived sulfides) are not synthesized in the body but derived from external sources. Sometimes an FMO substrate could come from both sources (e.g., phenethylamine or trimethylamine), and the definition of endogenous and dietary substances is somewhat ambiguous. Previously, the role of the metabolism of endogenous sulfur-containing substrates by FMO has been summarized [2]. Highly nucleophilic *S*-containing compounds can be substrates for FMO, including *S*-cysteine conjugates (i.e., mercapturic acids). Generally, however, mercapturates of xenobiotics are sufficiently polar to be excreted *per se*. It may be that highly lipophilic *S*-cysteine conjugates require additional metabolism by FMO to increase metabolite polarity for excretion [63]. Because the FMO oxygenation mechanism utilizes a peroxyflavin intermediate, if a sulfur-containing compound is treated with hydrogen peroxide in an enzyme model condition and produces an *S*-oxide

product, it is likely (barring steric limitations) that the compound will be a substrate for FMO. From the standpoint of drug development, such S-oxygenated thione products also have potentially interesting pharmaceutical and metabolic properties. Once formed, an S-oxide often possesses sufficient nucleophilicity to be S-oxygenated a second time, thus forming a thione S,S-dioxide. Generally, thione S,S-dioxides are more electrophilic than a thione S-oxide and can undergo reaction with nucleophiles, although thione S-oxides sometimes possess sufficient electrophilicity to be attacked by nucleophiles at the thione carbon atom. This has implications for predicting the toxicity of thione-containing compounds and their S-oxygenated metabolites. Often, if toxicity is observed with thione-containing compounds, it is associated with nucleophilic attack on electrophilic S-oxygenated metabolites and not necessarily with the parent compound. Neighboring atoms can control the electrophilicity of the oxygenated sulfur atom by either electron donation or electron withdrawal. For example, primary or secondary thioamides are more likely to form S,S-dioxides than simple thioketones because the neighboring nitrogen atom increases the nucleophilicity of the sulfur atom on the basis of resonance properties [64]. The thioamide nitrogen atom also helps stabilize the incipient S,S-dioxide by hydrogen-bonding interactions. Evidence for certain thione S-oxides (e.g., carbon disulfide) to form cyclic structures with the extrusion of elemental sulfur has been reported via a three-membered intermediate [65].

One important consideration in the overall metabolism, disposition, and toxicity of sulfur-containing compounds is the retroreduction of the S-oxide metabolite. An initial S-oxide metabolite of a thione is also electrophilic and can be attacked on the sulfur atom by thiophiles (Fig. 10.3).

An attack by a thiol generally results in the formation of a disulfide and liberation of water, and often the disulfide is converted to the parent compound (Fig. 10.3). Thioamide S-oxides can be retroreduced, and this process is also apparently dependent on the electron-donating versus electron-withdrawing nature of the neighboring groups. For example, the electron-deficient *para*-trifluoromethyl thiobenzamide S-oxide is metabolically retroreduced to its thioamide more rapidly than the electron-rich *para*-methoxy thiobenzamide S-oxide [64]. The oxygenation–reduction dynamic plays an important role in the potential for thione-mediated toxicity. For thione S-oxides that are efficiently retroreduced, less metabolite is available to proceed to the more electrophilic (and hence potentially more toxic) S,S-dioxide. A generality often observed is that decreased S,S-dioxide metabolite formation likely results in less potential for toxicity. Thioketone-containing compounds as well as other sulfur-containing compounds are also subject to autooxidation and from an analytical standpoint, this can be very challenging. In any case, it is important to clearly distinguish enzymatic from autooxidative processes in any metabolic incubation or biotransformation process.

Figure 10.3 S-Oxygenation of a thioamide to the sulfoxide, and thiophile attack by HSR' to ultimately reform the thioamide.

10.7.2 Thioamides

Thioamides are among the most efficiently metabolized substrates of FMO because of their pronounced nucleophilicity. But thioamide functionality generally does not appear in drugs to a great extent because of the potential for toxicity. Oxidative bioactivation of thioamides represents an example of a functional group that can produce toxicity, but this is dependent on a number of factors including steric constraints and electronic properties. S-Oxygenation of thioamides involves two sequential steps that afford *S*-oxide and subsequently *S,S*-dioxide as major metabolites (although the latter is generally too unstable to isolate and characterize). Thioamide S-oxygenation may be mediated by both FMO and P450s. An initially formed thioamide *S*-oxide metabolite is often relatively stable and in many cases isolable. Thioamide *S*-oxides possess capacity for toxicity because they are electrophilic but more likely because they are one step closer to a subsequent metabolite (i.e., thioamide *S,S*-dioxide) that is extremely chemically reactive. Thioamide *S*-oxides possess some potential toxicity in their own right because they are electrophilic enough to be attacked by thiophiles to form an imino disulfide (Fig. 10.3).

Reduction of the imino disulfide by glutathione would result in the formation of the parent thioamide but is wasteful to the cell because of the consumption of NADPH. In addition, the cell could become susceptible to toxicity under conditions where glutathione depletion was to occur. However, not all thioamide *S*-oxides are toxic likely owing to steric factors that prevent thiophile attack or decrease formation of *S,S*-dioxide formation [64]. Another factor that comes into play concerns the nucleophilicity of the *S*-oxide sulfur atom determined by neighboring electronic effects. If an *S*-oxide is relatively non-nucleophilic or electron deficient, the *S*-oxide sulfur atom can be the site for reduction. As discussed earlier, thioamides are generally not present in drugs to a great extent. However, some examples of second-line antitubercular drugs are available, including ethionamide and thiacetazone (a hydrazinecarbothioamide), that are sequentially S-oxygenated by the mycobacterial enzyme EtaA [66] as well as mammalian FMOs [67]. Like other thioamide *S*-oxides, ethionamide *S*-oxide has greater biological activity than ethionamide, but the observation of hepatotoxicity has limited its use clinically.

10.7.3 Thiols

Thiols are highly nucleophilic functional groups that probably do not occur extensively in drugs because of rapid metabolism. Thiols are substrates for FMO and are initially converted to the sulfenic acid (RSOH) [68]. Once formed, sulfenic acids can be attacked by thiophiles such as glutathione and rapidly converted to disulfides in the presence of thiols. Sometimes the disulfides are S-oxygenated one or more times to produce materials that can undergo additional transformations, both oxidative and reductive. In the case where the thiol that reacts with a sulfenic acid metabolite is glutathione, a mixed disulfide is formed, representing a detoxication process. The corresponding *S*-glutathione conjugate that is formed can be metabolized to a mercapturic acid. However, in the case where thiol S-oxygenation and glutathione attack are extensive, glutathione depletion can occur, and this may have toxicological consequences because glutathione depletion allows other electrophilic metabolites to accumulate. In the presence of depleted glutathione, additional metabolites that are sufficiently electrophilic could covalently modify important nucleophiles and lead to cell damage and

Figure 10.4 S-Oxygenation of thiol RSH to sulfenic acid, and retroreduction to the thiol via a disulfide.

eventually cellular necrosis. As discussed above, disulfide metabolites can be further oxygenated by FMO or other oxidases. In addition, disulfides can be reduced. This is another example of a futile metabolic cycle because the parent thiol is regenerated (Fig. 10.4).

In the case of FMO-mediated thiol S-oxygenation and subsequent reduction of the disulfide, the overall process consumes NADPH and potentially leads to loss of glutathione. Under such cellular conditions, glutathione needs to be biologically resynthesized, and hence, this overall process is physiologically wasteful. Disulfide S-oxygenation could also produce an electrophilic center (i.e., R-S-(O)-S-R) that is susceptible to further S-oxygenation and/or reduction. In addition, S-oxygenation of either a thiol or a disulfide affords susceptibility to displacement by another thiol (i.e., disulfide exchange). If the attacking thiol is a protein thiol, this could lead to protein disulfide formation and potentially could result in toxicological (or immunological) consequences. Disulfides arising from oxidation of thiol-containing xenobiotics that are recognized as foreign can elicit immune reactions and immunotoxicity. However, disulfides can be utilized as prodrugs in drug development. Because disulfide reduction in the body is relatively facile, thiol drugs can be liberated relatively efficiently. However, disulfide prodrugs have not been utilized that extensively, quite possibly because of the downstream metabolism outlined above. Thiols can be enzymatically S-methylated by an S-methyltransferase, and this tends to prolong the lifetime of a thiol-containing drug because of the types of metabolism available to the S-methyl functional group described below. An S-methyl metabolite is a thioether and, as discussed below, has attractive physiochemical and drug metabolism properties compared to the corresponding thiol drug. There are a few examples of endogenous thiol-containing substrates for FMO. Cysteamine is S-oxygenated to a sulfenic acid that is attacked by another molecule of cysteamine to produce the disulfide cystamine [69]. Currently, the physiological role of cysteamine S-oxygenation by FMO is not known but it could be involved in protein disulfide isomerization or FMO could have evolved as a general cellular protectant to ward the cell from reactive oxygen species by forming mixed disulfides [70]. It is interesting to speculate that cysteine conjugates of S-oxidative electrophiles produced by FMO (e.g., cysteamine) could serve as the necessary precursor for biosynthesizing glutathione because cysteine is an essential precursor that is transported into the cell to elevate cellular glutathione levels [2], and glutathione requires de novo synthesis after it is exported from the cell.

10.7.4 Thioethers

Thioethers possess many favorable druglike properties, and it is for this reason that the thioether functional group appears in many drugs. Replacement of a thiol with a thioether moiety in a drug candidate generally increases the lipophilicity of the parent drug, and because thioethers are typically not exceptional hydrogen-bond participants, this feature also contributes to improved cell permeability and bioavailability compared to the corresponding thiol. In addition to favorable physiochemical properties,

thioethers have beneficial metabolic properties. Barring steric constraints, lipophilic thioethers are generally good substrates for FMO, and S-oxygenation affords sulfoxides. When the two substituents adjacent to the sulfide are not the same, an enzymatically prepared *S*-oxide metabolite can possess a center of chirality [71]. Often, FMO catalyzes *S*-oxide formation with significant stereoselectivity. Of course, nonenzymatic oxidation (or autooxidation) of a sulfide with two different substituents can produce a racemic sulfoxide. In some cases, use of prochirality of a sulfide that produces an *S*-oxide with a center of chirality can provide information about the enzymatic process because often P450 and FMO work with opposite stereoselectivity [71]. Enzymatically formed *S*-oxides are zwitterionic in character and tend not to penetrate cells as efficiently as their parent sulfides. Consequently, sulfoxide metabolites can accumulate in cells and tend to have favorable cellular distribution if the target of the parent sulfide is inside the cell. This is because retroreduction of a sulfoxide inside the cell can elevate the relative concentration of a drug inside the cell. *S*-Oxides can be retroreduced to their sulfides, and this constitutes another example of a futile metabolic cycle. Aldehyde oxidase has often been implicated as the reductase for this process [72]. After retroreduction of an *S*-oxide to a sulfide, enzymatic reoxygenation completes the cycle and again tends to facilitate accumulation inside the cell, thus prolonging the action of the drug within the cell. In addition to retroreduction, *S*-oxide metabolites can be further oxidized to sulfones. Sulfone formation has been associated with FMO, P450, and other oxidases probably because the nucleophilicity is not always sufficient for FMO *S*-oxygenation. For FMO, the propensity for *S*-oxygenation of an *S*-oxide to a sulfone depends on the nucleophilicity of the *S*-oxide sulfur atom. In the case of P450, formation of sulfones from *S*-oxides involves additional considerations that are not easy to predict.

Sulfones tend to be relatively benign metabolites and are not reduced to their parent sulfides. However, there are examples of sulfones of aryl sulfides that participate in additional chemical and enzymatic transformations including displacement reactions. Unlike sulfoxides, sulfones are not charged and do not accumulate in cells to as great an extent compared with their corresponding sulfoxides. Sulfones do participate in extensive hydrogen bonding and thus possess slightly different permeability properties than sulfides.

Where a center of chirality can be formed on *S*-oxygenation, an investigation of the stereochemistry of the *S*-oxide itself should take place to rule out the role of autooxidation. In this regard, a chemical or biochemical method to produce sufficient amounts of the chiral *S*-oxide is desirable so that the chiral *S*-oxide can be incubated with the metabolic system to examine retroreduction and serve as a control for possible racemization. In the case of the sulfide cimetidine, the issue of enzymatic versus nonenzymatic oxidation was examined in some detail [73]. Cimetidine *S*-oxide is a prominent metabolite formed by FMO in humans. Although not explicitly studied, there is some evidence that cimetidine *S*-oxide is retroreduced to the sulfide or undergoes interhepatic recycling because pharmacokinetic studies in some humans show a biphasic profile [73]. It is notable that even HPLC grade solvents contain oxidizing agents, and solvents used in analytical work related to chiral *S*-oxide analysis and the like should be scrupulously treated to remove oxidizing agents, so that the analytical procedure does not contribute to confounding the determination of stereochemistry of the metabolite examined. As a practical matter, chiral HPLC and similar approaches

can be used to examine the contribution of enzymatic versus nonenzymatic oxidation as well as the stability of the *S*-oxide chiral center [71].

10.7.5 Sulfoxides

As discussed above, both P450 and FMO contribute to further oxidation of sulfoxides. One sulfoxide-containing chemical widely used in the drug discovery industry is dimethylsulfoxide (DMSO) and is worthwhile to discuss in some detail. With the advent of high throughput screening, DMSO has become a widely used vehicle to administer compounds for both *in vitro* and *in vivo* evaluation. This is because many compounds or closely related congeners from high throughput screening campaigns do not possess good solubility properties but are soluble enough in DMSO for *in vitro* evaluation or *in vivo* administration. The issue with *in vivo* administration of DMSO is that it is rapidly retroreduced to dimethylsulfide (DMS), which is an excellent substrate for FMO and is efficiently *S*-oxygenated by FMO. This sets up a metabolic futile cycle [74]. In addition, at the doses typically used as a vehicle for *in vivo* studies, DMS saturates FMO and effectively inhibits the enzyme as an alternate substrate competitive inhibitor. Thus, after administration to an animal, DMSO sets up a futile cycle, but because DMS is such a good FMO substrate, it effectively abrogates contribution to metabolism of most compounds coadministered with DMSO because (as discussed below) many of these compounds are amines. Thus, administration of DMSO (e.g., 1 mL/kg) to a small animal serves as a chemical knockdown that is similar to the more eloquent molecular knockout of FMO recently reported [75]. Generally, but not always, amines are poorer FMO substrates than DMS. From the perspective of evaluating the contribution of FMO in the metabolism of an amine drug candidate coadministered with DMSO, this represents quite a confounding situation. Likely, coadministration of an amine with DMSO will significantly decrease FMO-dependent metabolism of the amine. In addition, futile metabolic cycling of DMSO/DMS may also influence other NADPH-requiring metabolic pathways because of the consumption of NADPH in the reoxygenation of DMS. However, to my knowledge, this has not been extensively examined.

10.7.6 Amines

As a generality, nitrogen-containing functional groups are less nucleophilic than sulfur-containing ones, and while amines are well-recognized substrates for FMO, they tend to be *N*-oxygenated less efficiently than sulfur-containing substrates. Hence, avidity of an amine to FMO tends to be less, and, as a generality (although there are notable exceptions), K_m values tend to be greater for tertiary amines than for sulfur-containing FMO substrates. There are notable exceptions where amines are excellent substrates for FMO. In fact, the original name for FMO was *N,N*-dimethylaminoaniline-*N*-oxidase because *N,N*-dimethylaminoaniline was such a good substrate for the originally isolated FMO from pig liver [76]. Today, we recognize that FMOs *N*-oxygenate primary, secondary, and tertiary amines, depending on the form of the enzyme. Because many drugs employ amine functionality as an intrinsic part of their pharmacophoric composition, evaluation of the role of FMO in the metabolism of amines constitutes an important endeavor.

10.7.7 Hydrazines

Hydrazines comprise a group of highly nucleophilic nitrogen-containing compounds that are substrates for FMO. Metabolism of hydrazines by FMO illustrates a number of important points. Because of the lone pair on the adjacent nitrogen atom, the nitrogen atom that is oxygenated possesses increased nucleophilicity. This is the so-called alpha effect of the hydrazine nitrogen atom to oxygenation via a through-space lone pair–lone pair assisted mechanism. The alpha effect is also present in other molecules that have heteroatoms alpha to a nucleophilic center (i.e., hydroxylamines). Of course, the relative alpha effect for substituted hydrazines is dependent on the substituent pattern and the degree of electron-withdrawing or electron-donating properties of the neighboring substituents. For FMO-mediated N-oxygenation of substituted hydrazines, the extent of N-oxygenation may include some steric considerations. Generally, the tertiary nitrogen atom of a hydrazine is the site of N-oxygenation by FMO [77]. However, hydrazines are among the most toxic substances known, and extensive studies examining the role of human FMO in their metabolism have not been reported. Nevertheless, depending on the substitution pattern of the hydrazine, N-oxygenation could lead to several unusual azo metabolites and some of the metabolites could contribute to the toxicity of these compounds.

10.7.8 Hydroxylamines

Primary and secondary aliphatic amines are converted to hydroxylamines by FMO [17–19]. Generally, aliphatic hydroxylamines are more nucleophilic than the parent amine (because of the alpha effect), and often, they are N-oxygenated a second time to produce an *N,N*-dihydroxy intermediate that is not stable (Fig. 10.5).

In the case of primary amines, elimination of the elements of water produces an oxime. Both *cis*- and *trans*-oximes are capable of being formed from FMO, but often considerable stereoselectivity is observed [19]. Because loss of water from the *N,N*-dihydroxy intermediate is a spontaneous reaction and not strictly speaking enzyme

Figure 10.5 Sequential N-oxygenation of a cyclic secondary amine, with eventual ring opening and oxidation to the carboxylic acid.

catalyzed, it is somewhat surprising that very often a great degree of stereoselectivity in the FMO-derived product is observed. The large degree of stereoselectivity observed for oxime formation has been interpreted as an FMO enzyme “template effect” on product formation because the final oxime-forming reaction is not apparently FMO catalyzed [17,18]. It is also somewhat surprising that in the formation and disposition of aliphatic hydroxylamines, this transformation can go on in the presence of the strongly reducing environment of the cell. Like tertiary amine *N*-oxides, hydroxylamines can be efficiently retroreduced to the parent amine [78]. While the enzymatic basis for retroreduction of hydroxylamines is somewhat controversial (i.e., some favor a system of cytochrome *b*₅, NADPH-cytochrome *b*₅ reductase, and a P450, while others favor a hydroxylamine reductase), the fact that oxime formation can out-compete retroreduction suggests that FMO-mediated formation of oxime is quite robust. Similarly, formation of nitrones from aliphatic secondary hydroxylamines suggests that N,N-dihydroxylation of secondary hydroxylamines by FMO can effectively compete with hydroxylamine retroreduction (Fig. 10.5). An exhaustive examination of primary and secondary hydroxylamine retroreduction has not been reported. It is likely that different retroreduction systems are at work for different hydroxylamines (and for different tertiary amine *N*-oxides). But obviously, N-oxygenation may play a much larger role in primary and secondary aliphatic amine metabolism than previously recognized, if retroreduction is a facile process. It may be that considerable futile cycling occurs in many cycles of amine oxygenation and reduction. Because in some cases, the ultimate metabolite arising from FMO-mediated processes is quite distinct from the starting amine, careful evaluation of the metabolic pathway should be considered before the relative contribution of FMO in the metabolism of an amine is adjudged. For example, after formation of a nitron from a secondary amine, unless the nitron is highly conjugated or stabilized in some manner, it is prone to hydrolysis to the corresponding aldehyde and hydroxylamine [79]. Generally, because aldehydes are converted to carboxylic acids that are conjugated and excreted, this type of metabolism presents quite a distinct product metabolite profile compared to the starting amine. In the case of cyclic secondary amines, even more complex metabolites can be formed because of the propensity for cyclization and intramolecular reactions of the metabolites that are formed (Fig. 10.6).

Figure 10.6 N-Oxygenation of primary ($\text{R}' = \text{H}$) and secondary ($\text{R}' = \text{substituent}$) amine to *cis*- or *trans*-oximes and a nitron, respectively, via the intermediacy of a *N,N*-dihydroxy intermediate.

Regardless, and in agreement with tertiary amine metabolism, the role of FMO in primary and secondary aliphatic amine metabolism is potentially quite complex. Further confounding the metabolism of primary and secondary aliphatic amines is the role of retro-reductase systems in hydroxylamine (or tertiary amine *N*-oxide) retroreduction. Additional studies are needed to clarify the oxidative and retroreductive nature of primary and secondary hydroxylamine metabolism.

10.7.9 Cyclic Amines

Certain cyclic tertiary amines such as piperidines, piperazines, morpholines, and tetrahydropyridines are commonly found in biologically active drugs and drug candidates. Cyclic amines such as these are often found in drugs and drug candidates because of their favorable pharmaceutical properties and the propensity of pharmacological targets to bind these types of tertiary amines with high avidity. It is a common drug design strategy to decrease the metabolism of aliphatic secondary and tertiary amines and increase their bioavailability by incorporating the secondary and tertiary amines as a cyclic amine. In addition, other proximal substituents appended to the nitrogen atom or ortho to the nitrogen atom in the ring often further decrease metabolism and increase bioavailability. Sometimes, by decreasing metabolism via *N*-demethylation (in the case of aliphatic tertiary amines), *N*-oxygenation mediated by FMO (in the case of cyclic tertiary amines) becomes a more prominent metabolic pathway. One of the reasons for this is that cyclic tertiary amines such as piperidines are preferentially *N*-oxygenated by FMO because of the increased nucleophilicity of the tertiary amine. In the case of piperidines, for example, the through-space influence of the neighboring nitrogen atom lone pair increases the nucleophilicity of the tertiary amine. This is analogous to a through-space α effect discussed earlier for hydrazines and hydroxylamines. However, cyclic tertiary amines are not impervious to further metabolism, including *N*-demethylation. Cyclic tertiary amine *N*-oxides can also enter into further metabolism after retroreduction. After *N*-dealkylation, a des-alkyl cyclic amine metabolite can also, in principle, be a substrate for FMO (although it tends to be a less avid substrate than cyclic tertiary amines), but cyclic secondary amines can sometimes participate more in extensive metabolism than cyclic tertiary amines. This is particularly true in comparison to cyclic tertiary amine *N*-oxides (that, once formed *in vivo*, often possess sufficient water solubility to be directly excreted in the urine). For cyclic secondary amines, the initial FMO-dependent metabolism produces a hydroxylamine that often undergoes *N*-oxygenation a second time to afford an *N,N*-dihydroxy metabolite because the hydroxylamine is more nucleophilic than the parent cyclic secondary amine (Fig. 10.6).

Of course, this assumes that facile retroreduction of the cyclic secondary hydroxylamine does not occur to provide the parent amine. Nevertheless, the *N,N*-dioxxygenated metabolite is not indefinitely stable and eliminates the elements of water to afford a cyclic nitron. Generally, unless highly conjugated, nitrones are unstable to hydrolysis and result in ring opening to produce an aldehyde and a hydroxylamine (Fig. 10.6). Typically, the aldehyde and hydroxylamine portions of the metabolite undergo further metabolism. Sometimes, the ultimate metabolites are quite distinct from the structures of the initial metabolites and are not obviously related to classical FMO-mediated products. Considerable care needs to go into deciphering some of these more complex metabolic profiles.

10.7.10 Pyrrolidines

Cyclic tertiary amines such as pyrrolidines are also often N-oxygenated by FMO. Like some of the six-membered heteroatom-containing compounds discussed earlier, the compact structure of a pyrrolidine creates a pinned-back nitrogen atom lone pair that markedly increases the nucleophilic nature of the tertiary amine (e.g., N-oxygenation of nicotine is an example of a probe substrate of human FMO3 [80]). Similar to piperidine *N*-oxides, pyrrolidine *N*-oxides are relatively stable and in the *in vivo* setting are often excreted unchanged because of the polarity of the molecule. In principle, pyrrolidine *N*-oxides can be metabolically retroreduced in animals but this may be dependent on the route of administration; for example, a pyrrolidine *N*-oxide (e.g., nicotine-*N*-1'-oxide) administered i.v. is excreted unchanged [81] in humans but nicotine *N*-oxide administered orally to small animals is retroreduced [82]. One possible explanation to this phenomenon is that bacterial reductases of the gut reduce nicotine-*N*-1'-oxide after oral administration. The relative polarity and stability of cyclic tertiary amine *N*-oxides contribute to the lack of toxicity in these types of metabolites. While no evidence was observed for retroreduction of nicotine-*N*-1'-oxide after administration to humans [81], this is likely not the case for other cyclic tertiary amine *N*-oxides *in vivo*. However, the polarity of the *N*-oxide generally decreases pharmacological activity observed for the parent amine, and these types of metabolites are generally not potent and are excreted in the urine. Although there are some notable exceptions that tertiary amine *N*-oxides possess pharmacologic activity, it is unclear whether this is due to retroreduction to the parent amine or functional activity of the tertiary amine *N*-oxide in its own right.

10.7.11 Aliphatic Tertiary Amines

Aliphatic tertiary amines have long been associated as the prototypical FMO substrate. Conversion of tertiary amines to their *N*-oxide results in polar, readily excreted metabolites that are usually devoid of pharmacological potency. However, the zwitterionic nature of tertiary amine *N*-oxides can in some cases bestow pharmacological function. Although not extensively examined, aliphatic tertiary amine *N*-oxides can be retroreduced to the parent tertiary amine [5]. This is another example of a futile metabolic cycle. As described, the overall process consumes NADPH and leads to the regeneration of the tertiary amine. It is likely that many more examples of retroreduction of aliphatic tertiary amine *N*-oxides to tertiary amines have not been reported or observed due to analytical challenges or lack of direct evaluation. To date, a number of retro-reductases have been reported for tertiary amine *N*-oxides [83], and examples for tamoxifen *N*-oxide include aldehyde oxidase, cytochrome reductase, P450, and other various hemoproteins (e.g., hemoglobin and catalase) [84]. The importance of aldehyde oxidase as a general tertiary amine *N*-oxide retro-reductase is notable [85] because its presence in small animals is gender specific (i.e., males $\gg$ females) and estimates of the relative amount of tertiary amine *N*-oxides can be confounded as a consequence of gender [86]. Thus, comparison of metabolism between both genders can provide circumstantial evidence for the formation of tertiary amine *N*-oxides as well as evidence for retroreduction. Further confounding the situation for retroreduction of tertiary amine *N*-oxides is the observation that many commonly used drugs inhibit aldehyde oxidase [87].

Certain tertiary amines are prone to nonenzymatic autooxidation, and this can confound analysis of products formed and contribution of enzymes to the process. In the

case where *N*-oxide metabolites can produce a stereochemical outcome (e.g., in the case of *cis*- vs *trans*-nicotine-*N*-1'-oxide), ruling out the involvement of autooxidation is important for correct stereoselectivity determination. To prevent autooxidation in *in vitro* metabolic experiments, antioxidants such as DETAPAC can be added to the incubation [11]. DETAPAC is superior to EDTA because EDTA can also serve as a prooxidant under certain conditions and exacerbate the autooxidation situation.

10.7.12 Aliphatic Secondary Amines

Aliphatic secondary amines can be *N*-oxygenated by FMO to produce the hydroxylamine. The hydroxylamine metabolite, being more nucleophilic, is often *N*-oxygenated again by FMO to produce a nitron (after loss of water) because the hydroxylamine is generally a better substrate for FMO than the parent amine. Generally, aliphatic nitrones are unstable to hydrolysis and afford the aldehyde that can be further metabolized to a carboxylic acid and other metabolites. Hydroxylamines are also efficiently retroreduced to the parent amine. In the case of FMO-mediated *N*-oxygenation, *N,N*-dioxygenation affords a metabolite (i.e., a nitron after elimination of water) that is not subject to ready retroreduction. However, the initially formed hydroxylamine is efficiently retroreduced. For FMO substrates that do not desorb from the enzyme surface, substrates can be converted to nitrones without the intermediacy of retroreduction because the second *N*-oxygenation is kinetically faster than the initial one. In cases where steric inhibition to hydroxylamine *N,N*-dioxygenation is apparent, hydroxylamine retroreduction can be observed and little net *N*-oxygenation observed. To experimentally examine the role of retroreduction, saturating amounts of another hydroxylamine (e.g., dimethylamine hydroxylamine) can be added to the incubation to enable study of the test agent hydroxylamine formation. Other approaches to examining the role of retroreduction in secondary amine metabolism include varying the NADH/NADPH cofactor because certain retro-reductases preferentially require NADH to NADPH [88].

10.7.13 Primary Amines

Aliphatic primary amines are *N*-oxygenated by FMO. To date, compared with FMO1, FMO3 has shown much greater activity as a primary amine *N*-oxygenase. The initially formed hydroxylamine is more nucleophilic than the parent amine and is *N*-oxygenated a second time to an *N,N*-dioxygenated material. The *N,N*-dioxide is not indefinitely stable and eliminates the elements of water to produce an oxime as a stable metabolite (Fig. 10.5).

For sterically unhindered aliphatic primary amines, generally, the hydroxylamines are not observed because the second *N*-oxygenation is more efficient than the initial hydroxylamine formation. It is possible that an enzyme template effect is in operation for FMO-mediated oxime formation where the intermediate does not desorb from the enzyme surface until the oxime is formed. Because dehydration is fast and nonenzymatic for primary amine *N,N*-dioxygenated intermediates, the relative stereochemistry of the oxime formed is probably determined by a template effect and not via true enzyme catalysis [17,18]. Somewhat surprising to the nonenzymatic nature of the oxime formation process is that some primary oximes are formed with great stereoselectivity. In the case where this has been studied in detail, considerable stereoselectivity has been observed for a number of primary amine substrates [17,18].

In other cases, much lower stereoselectivity has been observed [19]. It is not clear as to the precise substrate structural features required that affect great stereoselectivity, but it underscores the utility of FMO in forming oximes from primary amines with sometimes considerable stereoselectivity.

10.8 NON-NUCLEOPHILES

In a few cases, relatively non-nucleophilic substrates have been reported to be oxygenated by FMO. Generally, non-nucleophilic substrate oxygenation by FMO is very rare, and considerable care needs to be applied to rule out nonenzymatic autooxidation. Another possible origin for FMO-dependent oxygenation of a non-nucleophilic substrate involves uncoupling of FMO (i.e., where the normal mechanism employing the peroxyflavin becomes uncoupled from the enzyme catalytic cycle and acts as a hydrogen peroxide generator to oxidize substrate). In the case where a center of chirality can be generated, a check of the stereochemistry of the product can indicate if uncoupling has occurred for FMO because if hydrogen peroxide or lipid peroxides are the oxidants, a racemic product will result. On the other hand, if a center of chirality can be formed, FMO produces products often with marked stereoselectivity [71]. If a center of chirality cannot be formed, standard incubation of FMO and comparison with the presence or absence of 3–5% hydrogen peroxide and product analysis can indicate if nonenzymatic hydrogen peroxide is responsible for product formation because racemic product will form in the case of the nonenzymatic process. Incubations in the presence of hydrogen peroxide alone will provide an indication of the nonenzymatic rate of oxidation. Of course, a true control incubation without hydrogen peroxide (and without NADPH) must also be run because certain hepatic microsome preparations (i.e., those that are prepared without antioxidants or at elevated temperatures) contain significant quantities of lipid peroxides that can readily autooxidize nucleophilic organic compounds. More complex experiments involving the use of $^{18}\text{O}_2/^{16}\text{O}_2$ and labeled water can help distinguish the role of FMO in substrate oxidation because FMO incorporates molecular oxygen and not water into enzyme-derived products. Thus, examination of a non-nucleophilic substrate in the presence of $^{18}\text{O}_2$ should show incorporation of 18-oxygen into the product if the product is formed in an NADPH- and FMO-dependent process. An oxidation product arising from aldehyde oxidase would incorporate oxygen from water and not molecular oxygen. Using commercially available recombinant FMO (e.g., BD Gentest, Woburn, MA) in these types of experiments would get around any potential confounding reaction with microsomal monooxygenases.

10.9 DRUG OPTIMIZATION

While functional groups primarily metabolized by FMO generally are not associated with apparent toxicity, there are a few such functional groups (e.g., thiones, thioureas, thioamides) that if present in a drug candidate likely should be replaced because of their propensity to cause toxicity via oxidative bioactivation. Generally, the corresponding oxygen-containing compound possesses less potential for toxicity. In principle, replacement of functional groups with pharmacophorically similar moieties that can be

metabolized to reactive metabolites by FMO should take place early in the development paradigm. Another strategy is to purposely introduce functional groups into drug candidates that are selectively metabolized by FMO. This approach would accomplish the objective of distributing the metabolism of the drug over a wider set of enzymes as well as potentially affording a variety of metabolites including FMO metabolites that are generally polar, nontoxic, and readily excreted. By avoiding metabolism (and bioactivation) by P450, the prospects for increasing the druglike properties of a drug candidate is likely increased. Because so many drugs are metabolized by P450 3A4, decreasing the amount of metabolism through this enzyme system is likely to decrease adverse drug–drug interactions. Enhancing the metabolism of a drug by FMO could take a few different forms. One approach might be to increase the propensity for FMO-mediated oxygenation, and another approach might be to decrease the reductive pathways that tend to decrease FMO product formation. Yet another method is to use a prodrug approach to fundamentally change the nature of the drug properties to improve some aspect of ADMET or bioavailability. A concept that has not been discussed herein could be to target drugs to different tissues by taking advantage of the distribution of FMOs. Because FMO1, for example, is prevalent in kidney and not present in adult human liver, developing drugs with FMO1 selectivity could potentially and preferentially target drugs to the kidney.

10.10 CONCLUSIONS AND FURTHER PERSPECTIVES

With the introduction of greater and greater numbers of preclinical drug candidates because of high throughput synthesis and screening, the bottleneck in drug discovery has shifted to include safety considerations. Applying metabolism and drug safety concepts earlier in the drug discovery and development process is likely to yield greater numbers of druglike materials that have a chance to become clinically useful agents.

One of the concepts presented herein is the idea that FMO can be utilized in the preclinical paradigm to facilitate the process of improved “hit” rate in drug discovery. FMO possesses some attractive features as a metabolic system: FMO is neither readily inhibited nor induced and the likelihood for adverse drug–drug interactions is likely decreased. It is likely that most of the variability of FMO is due to pharmacogenetics and genetic polymorphisms. As more clinical studies are done with drugs prominently metabolized by FMO, more information about the variability of FMO in the human setting will be revealed.

While not discussed to any great depth in this chapter, the structural biology of FMO has begun to show advances. Several crystal structures of FMO-like proteins have been reported, including the FMO from *Schizosaccharomyces pombe* [89], the FMO from *Methylophaga* sp. strain SK1 [90], and a Baeyer–Villiger oxidation catalyst called *cyclohexanone monooxygenase* from bacteria [91,92]. These FMO-like proteins are considerably smaller than mammalian FMOs; nevertheless, considerable new information has been forthcoming that can be related to the mammalian FMO structure and mechanism of action. In the future, additional progress with the structural basis of mammalian FMOs is anticipated, which will undoubtedly aid in understanding this important monooxygenase and designing new and more efficacious drug candidates.

11.1 SUMMARY

Molybdenum-containing enzymes represent a large and growing class of enzymes, which incorporate molybdenum, a transition metal as a biologically active cofactor. Nitrate reductase, sulfite oxidase, and the dimethylsulfoxide (DMSO) reductase family are of the most prominent in this class of enzymes. Of interest to drug research are the molybdo-flavoenzymes or molybdenum-containing hydroxylases, which not only need the molybdenum cofactor (MoCo) but also require a flavin cofactor for catalytic activity. These molybdenum-containing hydroxylases consist of mainly two enzymes from this class: aldehyde oxidase (AO) EC 1.2.3.1 and xanthine oxidoreductase (XOR) EC 1.2.3.2 [1], both enzymes being present in the cytosol of the cell and found in all vertebrates. AO and XOR catalyze both oxidation and reduction reactions, but the oxidation reaction has a higher degree of prevalence *in vivo*. The substrates for oxidation

by AO are N-heterocycles, iminium ions, and aldehydes, while XOR primarily oxidizes N-heterocycles. The reduction reactions include reductions of *N*-oxides, sulfoxides, hydroxamic acids, as well as, ring opening due to reductive cleavage. XOR is quite conserved among species and has consistent enzyme kinetics among species for a specific XOR substrate, xanthine. This may be because of its critical role in the catabolism of purines, putatively essential in the metabolism of xanthine to the terminal catabolite uric acid, its potential influence on the development of the mammary gland, and XOR's role in the longevity of lactation. AO, on the other hand, has multiple homologs, a broad substrate pool, varying kinetic parameters with the same substrate among species, and no pathophysiology has been associated with its absence. Recently, emphasis has been put on AO in drug research, due in part to two apparent reasons. The first reason is a perceived need during the early drug design phase of drug research to mitigate cytochrome P450 (CYP) metabolism in new compounds being considered for testing in clinical trials in an effort to achieve the required exposure in humans. Replacement of an aromatic substituent that can be rapidly metabolized by P450 (e.g., phenyl or naphthyl) with an azaaromatic (e.g., pyridyl, pyrimidyl, quinoliny) can lead to a decrease in P450 catalyzed metabolism but potentially introduce oxidation catalyzed by AO [2,3]. The second reason relates to the necessary use of azaaromatic chemical scaffolds in drug design, which happen to be AO substrates, but are required to achieve specific binding interactions at the site of a therapeutic target, such as specific kinases [4–6]. A switch in emphasis from P450 to AO moves drug researchers from a drug-metabolizing enzyme family for which there is much understood and numerous experiments and strategies already established to aid in drug design, cross-species correlations, predictions of human pharmacokinetics, drug–drug interactions, and so on to an enzyme family for which there is much less understood. For AO and XOR, there is a lesser understanding of abundance in tissues, little to no understanding of polymorphisms, no species that consistently translates to humans, and sheer complexity of the assembly of the enzymes. As science helps evolve our ability to incorporate these enzymes into drug research, strategies will become easier. In this chapter, a comprehensive summary of what is known from the peer-reviewed literature about these enzymes will be provided, with emphasis on the key understandings around the molybdenum-containing hydroxylases.

11.2 STRUCTURE AND FUNCTION OF MOLYBDENUM-CONTAINING HYDROXYLASES

Molybdenum-containing hydroxylases perform both oxidation and reduction reactions, but the oxidation reaction has a higher prevalence *in vivo*. Molybdenum is an indispensable component for this enzyme family and is necessary for catalysis along with flavin adenine dinucleotide. The oxidative hydroxylation catalyzed by the molybdenum is different from monooxygenases, in that, the molybdenum hydroxylase generates reducing equivalents during the hydroxylation process (e.g. not consume them), and the final source of the oxygen added to the substrate is from water, not molecular oxygen [7]. The reaction mechanism is discussed later in detail.

The primary physiological function of XOR has been understood for quite some time. XOR has a key role in the catabolism of purines, in which it oxidizes xanthine to hypoxanthine, then into the terminal catabolite uric acid [8,9]. The high kinetic efficiency of XOR to xanthine and hypoxanthine *in vitro* and *in vivo* provides evidence

that XOR would have significant activity toward drug-containing purine moieties. In mammals, XOR exists in two interconvertible forms, xanthine dehydrogenase and xanthine oxidase, the former predominates *in vivo*, although, the likely major role of XOR is purine catabolism. Of late, evidence has been growing that XOR has a broader biological role. One possible function stems from some observations that mice that are heterozygous for a loss of function in the XOR gene are not able to maintain lactation because of membrane defects in the milk fat droplets and mammary epithelial cell disruption [10]. This loss of function indicates that XOR may have a structural role in the development of the mammary gland. Higher levels of XOR have been observed in human colostrums, the fluid that is produced by mammals during the first two to three days post partum. This observation provided a hypothesis that newborn infants have a need for maternal XOR in the first few days of life, which may affect the absorption of dietary iron from the still developing gut of the infant [11,12]. Another possible function of XOR is antimicrobial properties by inhibiting bacterial growth *in vitro* via a nitric-oxide-dependent manner [13]. This antimicrobial role has extended to *in vivo*, where again infants that receive breast milk rich in XOR have less of a chance to develop gastroenteritis than those who are fed formula [14]. XOR has also been reported to generate superoxide radicals, which may also act beneficially as an antimicrobial agent [15]. The same beneficial aspect of superoxide radical formation has also been implicated in influencing the pathophysiology of alcohol-induced liver injury, ischemia reperfusion, endothelial dysfunction, hypertension, and heart failure [16,17]. However, the relevance to pathophysiology is somewhat speculative due to the large abundance of enzyme oxygen radical scavengers, such as catalase and superoxide dismutase (SOD), which should minimize the clinical effect.

The physiological function of AO is not completely understood. What is most known about AO is that it is involved in the metabolism of xenobiotics—specifically those containing aldehydes, iminium ions, and N-heterocycles are typical substrates in the oxidation reaction; and nitro-containing compounds, N-oxides, sulfoxides, hydroxamic acids, 1,2-benzisoxazole, and 1,2-benzisothiazole are typical substrates of AO reduction. Therefore, while it is not known, it is reasonable to assume that potential endogenous substrates may be similar in structural nature. One possible path to understand the function of AO is to recognize the tissue distribution of AO and infer mechanism. Putting this thought into practice, it has been reported that both AO and XOR are found in the skin. The function of these two enzymes in skin is still unknown, but possible functions could include elimination of biogenic waste or break down products formed by ultraviolet radiation or environmental stress and homeostatic control of vitamins [1,18]. Another possible function of AO is lipid homeostasis and lipid deposition. These links were observed through silencing the *Aox1* gene using siRNA in a 3T3-L1 mouse cell line. An arrest of the differentiation of the adipocyte was observed and a sequential diminished lipid accumulation resulted in the mice [19]. This observation was further supported in humans with a high level of AOX1 mRNA in human adipose tissue [19]. This proadipogenic link with AOX1 has been hypothesized to be a protein–protein interaction with the ABCA-1 lipid transporter [20,21] or, perhaps affecting the enzyme activity of PPAR γ and reducing the hepatic levels of AO [22].

AO has been suggested to influence the pathophysiology of numerous clinical disorders, although no direct link has been drawn. Renal toxicity is one disease that has been reported to be affected by AO oxidation due to AO generated toxic metabolites [23].

Two other clinical disorders hypothesized to be impacted by AO are amyotrophic lateral sclerosis (ALS) and alcohol-induced liver injury. It has been reported that the cause of the pathogenesis in these diseases is similar to what is believed for XOR, where the formation of oxygen radicals contribute to the manifestation of the disease [16,24,25]. Similar to the shortcomings of XORs link to disease pathophysiology, the linking of AO and oxygen radical formation to disease may also suffer from the vast abundance of oxygen radical scavengers in the liver, as well as other tissues in the body.

11.2.1 Classification and Structural Features

Mammalian AO and XOR are putatively similar in structure and considerable extrapolation of the biochemical properties of XOR has been done for AO. Overall similarity between AOX1 and XOR has been stated to be ~50% based on amino acid sequence [26]. Furthermore, the other AO forms that were discovered in mouse are even more homologous to AOX1 [27–29]. The enzymes exist as homodimers of subunits of ~150 kDa. Each monomer consists of three main domains: an 85-kDa portion containing the MoCo and substrate-binding sites on the C-terminal end, a 40-kDa FAD-containing domain in the middle, and a 20-kDa domain at the N-terminus that contains the two Fe–S clusters [1,30] (Fig. 11.1). However, it should be noted that during catalysis the passage of electrons occurs from MoCo to Fe–S to FAD, indicating that the protein must assume a tertiary structure that facilitates this order of transfer. The FAD-containing domain is where the transfer of electrons to oxygen occurs; however, for XOR when it is in the dehydrogenase form, this transfer occurs to NAD^+ .

Exploration of specific amino acids within the protein that contribute remarkably to enzyme function has been done. For example, AO activity has been shown to possess considerable variability across rat strains and among individual rats. These findings stimulated investigations into the amino acid sequence differences and revealed, for example, that conversion of glycine 110 to a serine was critical for high catalytic activity [31]. The glycine residue in the catalytically active enzyme is proximal to one of the Fe–S clusters, but its replacement with serine results in an inability to form a dimer, which is essential for catalytic activity [32]. Mutagenesis studies have yielded information regarding the roles of specific amino acid residues in substrate specificity. Mutation of human XOR to convert XOR to a protein that oxidizes AO substrates has been accomplished. Mutants in which either arginine 881 was altered to a methionine or glutamic acid 803 was altered to valine, diminished oxidation of hypoxanthine and xanthine, but activity toward benzaldehyde or cinnamaldehyde, was introduced [33]. Crystallography of the mutant XOR proteins revealed that large changes in conformation were not observed, and it was postulated that the arginine and glutamic acid side chains served in the formation of hydrogen bonds with the nitrogen and carbonyl oxygen atoms of purine substrates. The hydrophobic groups in the mutants no longer offer that H-bonding potential but instead permit the binding of hydrophobic aldehydes as substrates. Studies have also been done to compare substrate specificities among AO enzymes from different species. An investigation of rabbit/monkey chimeric proteins narrowed down the region of residues from 993 to 1088 in rabbit as important in cinchonidine oxidation. Replacement of individual amino acids of this region in monkey AO, which ordinarily metabolizes cinchonidine slowly, showed that a simple conversion of valine to alanine at position 1085 imparted activity, whereas the reverse for the rabbit enzyme (conversion of alanine 1081 to valine) removed the activity [34].

Figure 11.1 Monomeric unit of molybdenum-containing hydroxylases.

It is clear that the relatively recently acquired ability to express active AO to permit directed mutagenesis, coupled with the crystal structure of XOR (and perhaps AO in the future), will yield a much greater understanding of the roles of specific amino acids in the structure and activity of these enzymes [35–37].

While FAD and Fe–S clusters are common throughout enzymes, the MoCo is more unusual and merits a brief description. The structure of molybdopterin is shown in Fig. 11.2, and its elucidation was challenging because of its inherent instability on extraction from purified MoCo enzymes. Nevertheless, its structure elucidation represents a fascinating series of experiments and clever organic chemistry reasoning to solve this puzzle [38] (for a summary, see Leimkuehler *et al.* [39]). Much of the efforts to understand the biosynthesis of molybdopterin cofactors was obtained from bacteria as model systems, and thus must be extrapolated to mammalian systems. GTP is the common precursor. The synthesis of molybdopterin requires several enzymes catalyzing some unusual reactions, including those to add the two sulfur atoms to form the ethenedithiolate (which occurs via a thiocarboxylate on a terminal glycine of the enzyme itself), insert the Mo from molybdate, as well as sulfurase that adds the last sulfur (Fig. 11.2). The cofactor that is conjugated with cytosine monophosphate is putatively the one present in XOR and possibly AO, where as other organisms utilize other structures along this biosynthetic pathway in their respective MoCo enzymes. A detailed description of MoCo biosynthesis is described in Leimkuehler's work [39].

11.2.2 Mechanism of Catalysis

The reaction mechanism of molybdenum-containing hydroxylases has been studied extensively in XOR, and in general can be applied to AO. The reaction mediated by XOR consists of coupled reductive and oxidative half-reactions, therefore either oxidation or reduction of substrate has been observed in XOR/AO reactions. Figure 11.3 shows the redox state changes of XOR during substrate oxidation. Hydroxylation of a XOR substrate at the Mo binding site reduces Mo from VI to IV. Mo(IV) is then oxidized back to Mo(VI) via sequential electron transfer to the two Fe–S complexes. Further, electron transfer to FAD reduces FAD to FADH₂, which is oxidized back to FAD by O₂ to restore the enzyme to its original redox state. Kinetic studies have suggested that the different redox states are in rapid equilibrium [40–42]. The two Fe–S centers act as electron sinks to maintain Mo as VI and flavin in FADH₂ state for efficient reduction and oxidation.

Monooxygenases such as P450s oxidize substrate by incorporating oxygen atom from O₂ to the product. In contrast, the molybdenum hydroxylases use water as the ultimate source of the oxygen atom incorporated into the product [9,43], and generate reducing equivalents in the course of substrate hydroxylation (Fig. 11.3). Hydroxylation of XOR/AO substrates happens at the Mo center. Mo adopts a distorted square pyramidal coordination geometry, where the apical position is occupied by a Mo=O group and the four equatorial ligands are a terminal Mo=S group, two sulfurs from a pterin cofactor, and a ligand proposed to be hydroxide from water (Mo–OH) [44–48]. Previous studies have demonstrated that Mo–OH rather than the Mo=O is catalytically labile [7,49]. Oxidation of xanthine involves base-assisted nucleophilic attack on xanthine by the Mo–OH group with concomitant hydride transfer to the Mo=S group (Fig. 11.4). The concerted mechanism has been supported by both experimental evidence and computational studies [50–53]. A glutamate in the active site plays a central

Figure 11.2 Structure of molybdenum cofactors and the pathway of their biosynthesis.

Figure 11.3 Redox state changes of XOR during substrate oxidation.

Figure 11.4 A proposed reaction mechanism for the oxidation of xanthine by XOR.

role in catalysis. Mutation of this group to alanine decreases the enzyme reduction rate by a factor of 10^7 as compared with wild-type enzyme [51]. This glutamate is also preserved in AO. Both AO and XOR oxidize a wide range of N-heterocycles and aldehydes; however, XOR shows narrower substrate specificity than AO.

11.3 GENETICS OF MOLYBDENUM-CONTAINING HYDROXYLASES

As of 2011, there had been five known molybdenum-containing hydroxylases identified in mammals. Two of the five have been previously introduced in this chapter, human XOR and AO (AOX1). The other three were identified as related mouse proteins; AO homolog 1 (AOH1), AO homolog 2 (AOH2), and AO homolog 3 (AOH3) [1,54], currently known as AOX3, AOX4, and AOX3L1, respectively [1,55,56]. The solution of multiple molybdenum-containing enzyme crystal structures [45–47,54,57] has provided an understanding of protein folding and amino acid homology, and thus made tracing the evolution of molybdenum-containing enzymes easier.

In humans, only one expressed AOX gene (AOX1) is present, which differs in other mammals where multiple AOX homologs have been identified [55]. The AOX isoforms are expressed in specific tissues in different organisms, and are believed to recognize specific substrates and carry out different physiological responsibilities [54]. When AOX1 was first sequenced, it was apparent that the primary structure of the protein was quite similar to many mammalian XORs [26]. The amino acid sequences of AOX1

Figure 11.5 A comparison of aldehyde oxidase genes and pseudogenes present in the genomes of humans and commonly utilized animal models in pharmacokinetic and drug-metabolism studies. Orthologous genes are indicated in boxes of the same shade. Pseudogenes are indicated with an “x” through the box, and the species difference in chromosomal location is indicated on the right. *Source:* Adapted from the work of Garrattini and Terao [55,59].

and XOR from many different animal species can be easily aligned along the entire length [1]. As previously mentioned in Section 11.2.1, the similarity of AOX1 and XOR reaches ~50%, which indicates a common ancestral precursor [26,28,29]. When comparing the three mouse identified homologs of AO, a 63% amino acid homology is observed [1].

Since it is widely held that the eukaryote XOR coding region is the progenitor of all AOs, Rodriguez-Trelles *et al.* [58] provided a hypothesis of how these AOs came about. They hypothesize that AOs were created from two independent duplications of the progenitor XOR and further expressed, or not, because of species-specific evolutionary suppression or deletion events. It is also hypothesized that the duplication events occurred before species divergence, due to the high similarity among vertebrate orthologous proteins, and at the gene level, with the conserved exons of the three homologs of AOX observed in many mammals (Fig. 11.5) [1,55,59].

XOR has been identified in a very wide range of mammalia, and have been purified from liver and milk in bovine, human, rat, mouse, and rabbit. Regardless of the species and the source used for isolation, there is relatively little observed variability in the kinetic parameters (K_M or V_{max}) when measured using hypoxanthine or xanthine as a substrate [1]. Furthermore, allopurinol, a very selective tight-binding XOR inhibitor, inhibits all mammalian XORs, providing further evidence of extensive homology from species to species.

The human locus for XOR maps to chromosome 2p22 [60], which in mouse maps to chromosome 17 [61]. Other animal species of interest are rat, dog, and rhesus

monkey, which map to chromosomes 6, 17, and 13, respectively. The XOR genes of both human and mouse consist of 36 short exons and are 80 and 85 kb, respectively, in length. All of the exon/intron junctions of these two orthologs are completely conserved in both position and type. In comparison with the other organism, orthologs of XOR (i.e., *Aspergillus nidulans*, *Caenorhabditis elegans*, and insects such as *Drosophila melanogaster*, *Bombyx mori*, and *Calliphora vicina*, the number of exons in mammalian XOR genes is much larger, but the exon/intron junctions are concordant in the various species. This suggests a preserved code from a common origin. A few functional studies to define the regulatory elements of XOR in mammals provide that the 5'-flanking regions of the two genes are lacking a canonical TATA box, which is substituted by an initiator element [62,63]. These DNA regions contain most of the elements responsible for the constitutive expression of XOR, but do not seem to contain coding for tissue and cell specificity.

The gene structures of mammalian AO are quite similar to that of reptiles and birds but tend to diverge from that of insects and amphibians [27]. The disparate number of genes of AO in different mammalian species, as mentioned previously, is thought to be due to asynchronous duplication from a precursor XOR gene, which is further influenced by subsequent suppression and deletion events [58]. Evidence of this suppression is observed in humans. The complete Human *AOX1* is mapped to chromosome 2q32.3–2q33.1 [24]. Interestingly, the XOR gene is mapped to the same chromosome in humans, although this trait is uncommon in other mammalian species, except a close relative the Chimpanzee [59]. The human *AOX1* gene spans ~80 kb and contains 35 exons. Two pseudogenes, homologous to mouse *AOX3* and *AOX3L1*, have been identified in the same genomic region of chromosome 2 (Fig. 11.5). These pseudogenes named *duplication 1* (*dupl1*) and *dupl2* are the vestiges of *Aox3* and *Aox3L1*, which are transcribed to mRNAs that do not seem to code for protein products [59,64]. The observed suppression in humans is also observed in many preclinical species but to varying degrees among species (Fig. 11.5). With this variation, the prediction of human pharmacokinetics from preclinical species has proven challenging [55,59].

In humans, classical xanthinuria is a rare autosomal recessive metabolic disorder characterized by impairment of the final steps in the catabolism of purines; for example oxidation of hypoxanthine to xanthine and xanthine to uric acid by xanthine dehydrogenase. Consequently, classical xanthinuria manifests with diminished levels of uric acid and increased amounts of xanthine and hypoxanthine in the serum and urine. This displays itself clinically as a tendency to form xanthine stones in the urinary tract and xanthine precipitates in the muscles. There are two types of classical xanthinuria: type I that results from an isolated deficiency of XDH due to the autosomal recessive gene and type II that results from combined XDH and AO deficiency [65]. Xanthinuria type II has been connected with at least three individual single amino acid changes in the human molybdenum cofactor sulfurase (HMCS) gene [66–68], which when expressed catalyzes the conversion of the oxo- to the sulfido form of the MoCo required for the activity of XOR and AO. These mutations have obvious implications on XOR, because of the connection made between the HMCS expression and the lack of function. Since genetic deficiencies in the HMCS gene have not yet been associated with the pathophysiology associated with an AO related mechanism, it is hypothesized that AO is not essential for normal human function.

AO genes in other animal species' cluster are similar to what is observed in humans. In mouse, the clustering is close on chromosome 1 band c1, *Aox1* is on the most 5' end, followed by *Aox3*, 5 kb after, and then 15 kb *Aox4*, and 9 kb after *Aox311* [59,64] (Fig. 11.5). In rat, the same cluster of active genes is located on chromosome 9 [69], which has similar synteny to mouse. In dogs, there are two active genes in a cluster of four on chromosome 37. The two active genes are the orthologs of mouse *Aox4* and *Aox311*, and the other two stretches of DNA have homology to rodent *Aox1* and *Aox3*, but these sequences do not code for active protein [1,55,56]. In a review of AO by Garattini and Terao [55,59], some unpublished work had been reported, which claims that the rhesus monkey AO cluster is located on chromosome 12. Garattini and Terao's review also claims that the two genes that code for active protein are orthologous to those of mouse *Aox1* and *Aox311*, and the two nonexpressing pseudogenes are similar in DNA sequence to *Aox3* and *Aox4*.

11.4 BIOTRANSFORMATIONS OF XENOBIOTICS BY XOR AND AO

Oxidation by XOR/AO involves nucleophilic attack at an electron deficient carbon, which in turn provides the insertion point of an oxygen atom to generate a carboxylic acid from aldehydes or a lactam from aromatic N-heterocycles. Both AO and XOR reduction occur at either N- or S-functional groups under anaerobic or hypoxic conditions, providing that an appropriate electron donor is present. In regard to AO, the appropriate electron donor is either benzaldehyde or 2-pyrimidinone, or other oxidized substrate; and for XOR, the electron donor is xanthine. Reduction rates are dependent on both the concentration and availability of the electron donor. Some known reduction reactions include reductions of *N*-oxides, sulfoxides, nitro-containing compounds, hydroxamic acids, as well as reductive ring opening of heterocycles. These metabolic routes attributed to XOR and AO will be elaborated on in the following sections.

11.4.1 Oxidation of Aromatic N-Heterocycles

Oxidation of N-heterocycles accounts for a majority of AO/XOR-mediated reactions. A recent survey of several current compound collections showed that 35–56% of the compounds in these collections are potential AO/XOR substrates based on the presence of an unsubstituted aromatic carbon atom adjacent to the nitrogen [2]. Figure 11.6 is a summary of heterocyclic cores that are reported to be oxidized by AO/XOR. Simple unsubstituted N-heteroaromatics such as imidazole, pyrazole, pyridine, pyrazine, and pyrimidine are not readily oxidized by XOR/AO. Substituted pyridines are more easily oxidized by AO (Fig. 11.7). Both metyrapone [70] and 1,2-bis(nicotinamideo)propane were oxidized to pyridone at the α -position [71]. A methylpyridine group in a TLR7 agonist has also been shown to be oxidized to α -pyridone by AO [72].

Substituted pyrimidines such as 2- and 4-hydroxypyrimidine were readily oxidized by AO to form uracil, the former being widely used as an electron donor for AO reduction studies *in vitro*. The conversion of hydroxypyrimidine to uracil by AO has been utilized to oxidize several 5-substituted hydroxypyrimidine (5-fluoro- and 5-ethynyl-2-pyrimidinone, Fig. 11.8) to the corresponding pyrimidine nucleoside bases to overcome low and/or inconsistent oral bioavailability of this compound class

Figure 11.6 Typical aromatic heterocyclic cores in AO/XOR substrates.

Figure 11.7 Pyridine-containing substrates of AO/XOR (arrow indicates the site(s) of oxidation).

[73,74]. This prodrug approach has also been employed in the bioactivation of 5-iodo-2-pyrimidinone-2'-deoxyribose (IPdR) to 5-iodo-2'-deoxyuridine (IUdR) [75,76] and zebularine to uridine [77]. FK3453 is an adenosine A1/2 dual inhibitor for the treatment of Parkinson's disease. Despite its satisfactory absolute bioavailability and total body clearance in animals, the plasma concentrations of FK3453 in humans were extremely low. This was attributed to AO metabolism where an oxidative metabolite of the 2-aminopyrimidine moiety was identified as a major metabolite [78]. RS-8359 is a selective and reversible MAO inhibitor containing 4-aminopyrimidine. Itoh *et al.* [79] showed that AO exhibited stereoselectivity for the S-enantiomer in rat *in vitro* (Fig. 11.9). The stereoselective AO metabolism was also observed *in vivo*. After oral administration of racemic RS-8359 to rats, mice, dogs, monkey, and humans, plasma concentrations of the R-enantiomer were substantially higher than those of the S-enantiomer [80].

The fused-ring analogs are typical targets for oxidation by AO/XOR. Fusion of benzene rings to pyridine such as quinoline, isoquinoline, and phenanthridine increases

Figure 11.8 Pyrimidine substrates of AO/XOR (arrow indicates the site(s) of oxidation).

Figure 11.9 Stereoselective oxidation of RS-8359 by AO.

Figure 11.10 Quinoline and isoquinoline substrates of AO/XOR (arrow indicates the site(s) of oxidation).

binding to rabbit liver AO [81] (Fig. 11.10). Quinoline and isoquinoline have K_m values of 3 and 0.2 mM, respectively, while phenanthridine has higher binding affinity toward AO (K_m , 2.3 μ M), which could be due to the increased lipophilicity that facilitates substrate binding to the active site. Interestingly, although phenanthridine, 3,4-benzoquinoline, is a good AO substrate, 5,6- and 7,8-benzoquinoline do not bind to the enzyme [82]. The AO oxidation of acridine is unusual in that hydroxylation takes place at carbon para position rather than ortho to the nitrogen atom [83]. The normal oxidation position, ortho to the nitrogen, is not available for enzyme attack. Similarly, the acridine anticancer agent *N*-[(2'-dimethylamino)ethyl]acridine-4-carboxamide (DACA) is rapidly converted to the acridone by human, rat, and guinea pig AO [84]. Quinine, quinidine, cinchonine and cinchonidine, four quinoline-based antimalarials are all oxidized at the quinoline ring by AO [85]. The oxidation rates of quinine and quinidine were lower than those of cinchonine and cinchonidine, probably because of the electron-donating 6'-methoxy group. Stereoselective metabolism by AO was observed for the two pairs of stereoisomers: cinchonidine and quinidine were oxidized at much higher rates than their corresponding stereoisomers, cinchonine and quinine [86]. SGX523, a quinoline-containing c-MET inhibitor in clinical development for the treatment of solid tumors, was oxidized by AO to a 2-hydroxyquinoline metabolite [23]. This metabolite has low solubility and was excreted in urine, and was suspected to form crystal deposits in renal tubules to compromise renal function in patients. The selective dopamine D3 receptor antagonist SB-277011 is another quinoline-containing compound. SB-277011 was predominantly metabolized by AO and its clearance value in human liver homogenates was 35-fold higher than that in microsomes [87]. Zoniporide, a quinoline-containing inhibitor of the sodium/hydrogen exchanger, was mainly cleared via metabolism, and the major excretory and circulating metabolite in humans was 2-oxozoniporide formed by AO [88].

Quinazoline and phthalazine, cinnoline, and quinoxaline (benzene-fused pyrimidine, pyrazine, and pyridazine) are oxidized by AO to the lactam metabolites (4-hydroxyquinazoline, 2,4-di-hydroxyquinazoline, 1-hydroxyphthalazine, 4-hydroxy-

cinnoline, 2-hydroxyquinoxaline, and 2,3-dihydroxyquinoxaline) [81] (Fig. 11.11). These compounds are weak XOR substrates. Ghafourian *et al.* [89,90] have studied the quantitative structure–activity relationship (QSAR) of phthalazine and quinazoline derivatives and the influence of substituents on AO-mediated oxidation, utilizing kinetic data reported previously. Their studies suggest that polarity of phthalazines had a negative effect on the enzyme activity, leading to the reduction of $V_{\max}$ and increase of K_m . Electron-withdrawing substituents at 2- or 4-position of quinazoline favored the AO oxidation. Carbazeran, a phthalazine-containing inotropic agent, is primarily metabolized by AO in humans to the phthalazinone. The oral bioavailability in man was too low to be measurable, although oral bioavailability in dog was ~68% because of low AO activity in dogs [91,92]. Bromidine, a quinoxaline-containing potent ocular hypotensive agent, has been shown to be metabolized by AO to quinoxaline-2,3-dione and two isomeric quinoxalinone in both ocular tissues and liver fractions [93,94]. A potential new anticancer agent XK-469 underwent extensive metabolism in human hepatocytes and in a phase 1 patient study. An oxidized product at C-3 of quinoxaline formed by AO was the predominant metabolite both *in vitro* and *in vivo* [95]. Bicyclic heteroaromatic moieties in molecules as big as macrolides can be metabolized by AO. The 1,8-naphthyridine ring system in compound **1** was shown to be vulnerable to AO in human liver cytosol. Addition of 3-hydroxyl group (compound **2**) failed to improve AO metabolic stability. However, the 1,5-naphthyridine from rearrangement of nitrogen in the ring (compound **3**) was stable in human liver cytosol [96].

Pteridines are readily oxidized by AO/XOR. Of the four carbons adjacent to the nitrogens, 2, 4, 7, but not 6 are oxidizable. Multiple oxidations can happen in pteridine (Fig. 11.11) [97,98]. However, XOR is more active in carrying out the sequential oxidation. For example, 2- and 7-hydroxypteridine were oxidized by XOR but not AO. *In vitro* studies suggest that XOR may predominate pteridine metabolism; however, methotrexate, a potent inhibitor of dihydrofolate reductase for the treatment of leukemia, was metabolized by AO [99,100]. A major metabolite of methotrexate is its 7-hydroxylated derivative.

Purine was rapidly oxidized by XOR and AO (Fig. 11.12). Purine is sequentially oxidized via hypoxanthine and xanthine to uric acid [8]. XOR is more efficient in catalyzing this sequential reaction than AO. 6-Mercaptopurine is oxidized to 6-thiouric acid via 6-thioxanthine. The first and rate limiting step in this biotransformation is catalyzed solely by XOR, whereas both XOR and AO are involved in the oxidation of 6-thioxanthine to 6-thiouric acid [101]. 6-Mercaptopurine is subject to a large drug–drug interaction when coadministered with allopurinol, a specific XOR inhibitor [102]. AO shows broader substrate specificity and oxidizes a wide variety of drugs containing purine. Both famciclovir and its deacetylated metabolite 6-deoxypenciclovir are efficient substrates of AO; however, they show little activity with XOR [103,104]. AO appears to preferentially oxidize the 8-carbon (Figure 11.13). When dosed intravenously, which bypassed intestinal XOR, both 6-mercaptopurine and 6-thioguanine were oxidized to 8-oxo metabolites, presumably catalyzed by AO [105,106]. Similarly, *O*⁶-benzylguanine is oxidized at 8-carbon by human AO [107]. Krenitsky *et al.* [98] studied a series of substituted purines. While an electron-withdrawing (CONH₂, CN) or neutral (CH₃) substituent at the 6-position of purine maintained the rate of AO metabolism, an electron-donating group (NH₂, OH, SH) rendered the purine significantly less reactive (Table 11.1). Electron-donating 8-substituents also decreased AO metabolism; however, the same effect was not observed for electron-donating groups at

Figure 11.11 Quinazoline, phthalazine, cinnoline, quinoxaline, and pteridine substrates of AO/XOR (arrow indicates the site(s) of oxidation).

the 2-position of purine. The trend is less clear for XOR metabolism of purine analogs (Table 11.1).

In addition to the cores described above, there are other heterocyclic AO substrates reported in the literature (Fig. 11.14): pyrolopyrimidine (zaleplon) [108], dibenz[*b, f*]-1,4-oxazepine [109], azabenzimidazole (a gp120-CD4 inhibitors) [110], pyrazolo-triazine (a GABA_A 5 inverse agonists) [111], and 8-azaquinazolinone (a CXCR3 antagonists) [112].

11.4.2 Aldehyde Oxidation

AO/XOR catalyzes the oxidation of aldehydes to carboxylic acids. Generally, drugs rarely contain an aldehyde moiety; however, aldehydes can be intermediate metabolites of alcohols. Hence AO/XOR may be involved in sequential metabolism of alcohol (the same reaction can be catalyzed by aldehyde dehydrogenase). Reactive oxygen species (ROS) such as H₂O₂ and superoxide are the byproducts of AO oxidation (Fig. 11.1). Increased generation of ROS during ethanol metabolism is proposed to

Figure 11.12 Purine substrates of AO/XOR.

contribute to alcohol-related oxidative injury to liver and pancreas [113,114]. Both aliphatic (i.e., retinal) [115] and aromatic aldehydes are oxidized by AO/XOR to the corresponding carboxylic acids. Lipophilicity appears to enhance aldehyde binding to AO, as a result, many aromatic aldehydes are excellent substrate for AO (Fig. 11.15), such as benzaldehyde, indole-3-aldehyde, vanillin, and pyridoxal [116–118]. However, these aromatic aldehydes are poor substrates of XOR.

Acid metabolites of drugs were reported to be formed by AO (Fig. 11.16). For example, tolbutamide is hydroxylated to the benzyl alcohol, by P450, further oxidized into an aldehyde by alcohol dehydrogenase and finally oxidized to the carboxytolbutamide metabolite by AO [119]. Tamoxifen is oxidized first by monoamine oxidase (MAO) to an aldehyde intermediate and subsequently oxidized to the corresponding carboxylic acid by AO [120]. Similarly, the antidepressant citalopram is oxidized by MAO to an aldehyde and further oxidized by AO to a carboxylic acid metabolite [121].

11.4.3 Oxidation of Iminium Ions

Iminium ions, with a positive charge on the nitrogen atom of C=N, facilitates nucleophilic attack to the C=N bond, therefore, they are excellent substrates for AO. For example, *N*¹-methylnicotinamide, which is formed by the N-methylation of nicotinamide by methyltransferase, can be oxidized by AO [122,123]. Both 2- and 4-carbons

Figure 11.13 8-Oxidation of purine analogs by AO.

have been shown to be oxidized to form 2- and 4-pyridone, respectively, however, the ratio of pyridone metabolites varies among species [124,125]. Human AO oxidizes *N*-methylnicotinamide mainly to 2-pyridone, whereas mouse AO generates equal amounts of 2- and 4-pyridone (Fig. 11.17) [126].

Iminium ions can be generated as intermediates during the metabolism of cyclic amines such as pyrrolidines, piperidines, indoles, and dihydropyridines via CYP450 or monoamine oxidase. These iminium ions are highly reactive species and can cause toxicity [127]. AO oxidizes these iminium intermediates to lactams, which represents an important detoxification pathway for these compounds. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is an exogenous neurotoxin whose neurotoxicity is believed to be mainly because of 1-methyl-4-phenylpyridinium (MPP). MPP is generated through sequential oxidation via an intermediate 1-methyl-4-phenyl-2,3-dihydropyridinium species (MPDP). AO is one of the major enzymes, which catalyzes conversion of MPDP to MPTP lactam and therefore decreases the formation of MPP (Fig. 11.18) [128–130].

AO is involved in the formation of a number of lactam drug metabolites. For example, nicotine iminium, which is formed from P450-mediated oxidation of nicotine, is converted to cotinine by AO (Fig. 11.19) [131]. Similarly, ABT-418, prolintane, and azapetine undergo initial P450-mediated oxidation to iminium ions and further AO-mediated oxidation to lactams [132].

TABLE 11.1 Relative AO/XOR Activities of Some Purine Analogs

Purine						
AO activity	100	82	94	280	2	3
XO activity	100	<3	164	8	6	130

Purine						
AO activity	16	<1	<1	140	38	43

Figure 11.14 Other heterocyclic AO substrates (arrow indicates the site(s) of oxidation).

11.4.4 Reduction

AO/XOR-mediated reductions of nitro groups, *N*-oxide, nitrate, hydroxamic acids, oximes, isoxazoles, and isothiazoles have been demonstrated *in vitro*. However, the extent to which these reductions are actually carried out by AO *in vivo* is difficult to assess. This is because of several reasons: (i) *in vitro*, the incubations must be done under anaerobic conditions, as the substrate is taking the place of oxygen, (ii) electron donors such as *N*¹-methylnicotinamide are required *in vitro*, however, such cofactors are not identified *in vivo*, (iii) often other reducing enzymes such as P450 reductase, NADPH-benzoquinone reductase, and a recently identified molybdenum-containing mitochondrial amidoxime reducing component (mARC) can catalyze the same reduction.

11.4.5 Nitroreduction

AO and XOR are involved in nitroreduction of nitro-containing compounds (nitrated polycyclic aromatic hydrocarbons, nitrofurans, and nitroimidazoles). These nitro-containing compounds are generally mutagenic and nitroreduction is responsible for their mutagenicity. Nitroreduction is a sequential one- and/or two-electron reduction process, which generates reactive intermediates as well as ROS (Fig. 11.20). Both

Figure 11.15 Aliphatic and aromatic aldehyde substrates of AO/XOR.

Figure 11.16 Examples of drugs that undergo sequential aldehyde oxidation by AO.

nitroso and *N*-hydroxyamino metabolites are potential electrophiles; however, only the latter derivative appears to modify DNA [133].

Nitroreduction of nitrated polycyclic aromatic hydrocarbons (2-nitrofluorene, 1-nitropyrene, and 4-nitrobisphenyl, Fig. 11.21) in animal livers has been investigated extensively, and it was reported that the reductive metabolism of these compounds is catalyzed by cytochrome P450, P450 reductase, and AO/XOR in mammalian liver [134]. Nitroheterocycles such as nitrofurazone, metronidazole, and benznidazole (Fig. 11.21) underwent XOR/AO-mediated nitroreduction under anaerobic condition

Figure 11.17 Oxidation of *N*¹-methylnicotinamide by AO.

Figure 11.18 Detoxification of MPTP by AO.

[135]. P450 reductase also participated in the reaction. A number of nitroguanidine and nitromethylene insecticides have been reported to undergo nitro group reduction by rabbit liver AO. The nitro groups of clothianidin and imidacloprid was reduced by rabbit AO to nitroso and amino groups [136,137].

11.4.6 Reduction of Nitrates and Nitrites by XOR

XOR catalyzes reduction of organic and inorganic nitrates and nitrites to nitric oxide (NO). It is suggested that XOR may be an important enzyme system that produces

Figure 11.19 Examples of lactam metabolite formation via AO oxidation of iminium (arrow indicates site of oxidation).

Figure 11.20 Proposed mechanism of AO/XOR reduction of nitro-containing compounds.

vasorelaxation NO via reduction of organic nitrates and nitrites such as glyceryl trinitrate, isosorbide dinitrate, isoamyl nitrite, and isobutyl nitrite (Fig. 11.22) [138–140].

11.4.7 N-Oxide and Sulfoxide Reduction

AO acts as reductase for *N*-oxide and sulfoxide under anaerobic conditions (Fig. 11.23). Nicotinamide *N*-oxide, *S*-(–)nicotine-1'-*N*-oxide, imipramine *N*-oxide, and cyclobenzaprine *N*-oxide are reduced to their corresponding parent amines when incubated in liver cytosols from rabbits, hogs, guinea pigs, hamsters, rats, and mice [141,142]. XOR also reduces *S*-(–)nicotine-1'-*N*-oxide to nicotine *in vitro* [143]. Sulfoxides (sulindac, sulfinpyrazone, phenothiazine sulfoxide, fenthion sulfoxide) are reduced by AO to their corresponding sulfides under anaerobic conditions [144–149]. Stereoselective reduction of sulfoxide has been reported for flosequinan, a racemic mixture of *R*- and *S*-sulfoxide, both rat liver and kidney cytosol reduced *R*-sulfoxide much faster than *S*-sulfoxide to the sulfide metabolite under nitrogen in the presence of electron donor 2-hydroxypyrimidine (Fig. 11.24) [150]. Both reduced amine and sulfide metabolites can be oxidized back to *N*-oxide and sulfoxide, which may prolong the residence time of these species via futile cycle of oxidation–reduction.

Figure 11.21 Examples of nitro-containing substrates of AO/XOR.

Figure 11.22 Organic nitrates and nitrites that are reduced by XOR to generate NO.

11.4.8 Reduction of *N*-Hydroxy Compounds

The reduction of *N*-hydroxy compounds such as hydroxamic acids, oximes, and *N*-hydroxyguanidines by AO/XO have been described in previous reviews [126,151]. Hydroxamic acids such as benzohydroxamic acid, nicotino hydroxamic acid, salicylhydroxamic acids, and *N*-hydroxy-2-acetylaminofluorene are reduced to their corresponding amide by AO [152,153] (Fig. 11.25). Guanoxabenz, an *N*-hydroxyguanidine metabolite of antihypertensive drug guanabenz, is reduced back to guanabenz by XO [154]. Acetophenone oxime and salicylaldoxime are reduced by AO under anaerobic

Figure 11.23 AO/XOR reduction of *N*-oxide and *S*-oxide compounds.

conditions to their corresponding ketimines, which are hydrolyzed to the oxo metabolites, whereas benzamidoxime is reduced to a ketimine [155]. Reduction of *N*-hydroxy groups is not limited to AO/XO. Recently, a new molybdenum-containing enzyme system named *mitochondrial amidoxime reducing component* (mARC) was reported to be involved in microsomal and mitochondrial reductions of hydroxylamines and amidoximes [156–158].

11.4.9 Heterocycle Reduction

AO has been suggested to be involved in the reduction of 1,2-benzisoxazole and 1,2-benzisothiazole in some drugs (Fig. 11.26). The 1,2-benzisoxazole ring of zonisamide was reductively cleaved to the ketimine intermediate, which is hydrolyzed to a keto metabolite in rat and rabbit liver cytosol [143]. It should be noted that the reductive

Figure 11.24 Stereoselective reduction of sulfoxide in flosequinan.

Figure 11.25 Reduction of *N*-hydroxy compounds by AO/XOR.

metabolism of zonisamide is also catalyzed by liver microsomal cytochrome P450, especially CYP3A4 [159], as well as mammalian intestinal bacteria [160]. Similarly the 1,2-benzisothiazole of ziprasidone underwent reductive cleavage of N–S bond to form a thiol intermediate. Subsequent S-methylation of the produced thiol moiety yielded a major metabolite *in vivo* [161]. *In vitro* studies suggested that AO is the major enzyme responsible for the reductive metabolism of ziprasidone [162,163].

Figure 11.26 Heterocycle reduction catalyzed by aldehyde oxidase.

11.5 INHIBITORS OF MOLYBDENUM-CONTAINING HYDROXYLASES

11.5.1 Inhibitors of AO

11.5.1.1 In Vitro. Many inhibitors of the molybdenum-containing hydroxylases have been characterized and reported in the literature. Menadione is perhaps one of the most well-characterized inhibitors of AO, particularly *in vitro*, that does not potently inhibit XOR [164]. Thus, it is often used to distinguish between AO- and XOR-mediated metabolism in cytosolic or S-9 fractions [23,78,84,165]. Meanwhile, the use of menadione as an inhibitor of AO *in vivo* is unlikely to be effective since it is rapidly reduced by DT-diaphorase [166]. Menadione has been observed to be roughly equally potent against AO in multiple species [84,167], whereas other inhibitors of AO appear to show profound species differences for inhibitor potency. For example, estradiol was found to inhibit vanillic acid formation from vanillin in liver cytosol from human, monkey, rat, and mouse at potencies ranging from IC_{50} of 0.3 μM (human) to 12 μM (monkey) [167]. In addition, methadone and SKF-525A inhibit rat AO, with little inhibition of human AO [84,168]. These findings suggest that it is unlikely that inhibition of AO in a particular species can be directly extrapolated to human AO.

In perhaps the most comprehensive attempt to screen for inhibitors of AO, Obach *et al.* [169] tested 239 frequently used drugs for inhibition of AO utilizing phthalazine oxidation to phthalazinone as a probe reaction. One of the more interesting findings from these studies was that among the inhibitors tested, raloxifene was found to be exquisitely potent ($IC_{50} = 2.9$ nM). Other drugs from a similar therapeutic class were also identified as inhibitors, including tamoxifen, ethinyl estradiol, and estradiol, and overall, 16 drugs were found to inhibit AO with an $IC_{50} < 1$ μM . Overall, there was no one particular physical property that distinguished the most potent inhibitors from the weakest ones, although most inhibitors were weakly basic in nature. From a structural perspective, a tricyclic moiety was present in many potent inhibitors, including several tricyclic antidepressants, antipsychotic agents, and phenothiazines. Of these, perphenazine was found to be the most potent ($IC_{50} = 33$ nM). Other inhibitors of AO discovered in these studies worth mentioning (Fig. 11.27) are the potent CYP3A4

Figure 11.27 Inhibitors of aldehyde oxidase.

inhibitor ketoconazole ($IC_{50} = 3.5 \mu M$) and the CYP3A time-dependent inhibitor erythromycin ($IC_{50} = 15 \mu M$) and verapamil ($IC_{50} = 3.5 \mu M$). Most recently, it has been highlighted that flavenoids, one of the largest groups of naturally occurring compounds that have been shown to modulate the activity of several drug-metabolizing enzymes, may also be effective inhibitors of AO [170,171].

As previously discussed, distinguishing AO from XOR-catalyzed reactions is relatively straightforward, as menadione selectively inhibits AO and not XOR. Raloxifene has also been found to selectively inhibit AO [172], and has been used to confirm the role of AO in the oxidation of zoniporide and zebularine [77,88]. However, when attempting to differentiate AO from cytochrome P450-mediated oxidations in more enzymatically complete systems such as hepatocytes, raloxifene likely does not possess the desired selectivity, as it is known to be potent time-dependent inhibitor of CYP3A4 [173]. In addition, menadione appears to be fairly nonselective for inhibiting AO, as it also crosses over to inhibit multiple P450 isoforms (unpublished observations, R.S. Obach). In contrast, hydralazine is reported to be a potent inhibitor of AO, both *in vitro*, and *in vivo* in rabbit [174] and guinea pig, where it was used to demonstrate the role of AO in the extensive first-pass metabolism of carbazeran [175]. Hydralazine apparently does not inhibit the cytochrome P450 enzymes (unpublished observations, R.S. Obach) [176], which makes it a potentially useful *in vitro* tool for the selective inhibition of AO in effort to understand the fraction of metabolism mediated by AO

compared to the cytochrome P450 enzymes for drugs that may have both pathways contributing to their total metabolic clearance.

11.5.1.2 In Vivo Drug–Drug Interactions. From a clinical standpoint, only one drug interaction has been attributed to inhibition of AO [177]. In a study in human volunteers, following an 800-mg oral dose of cimetidine, the oral clearance of zaleplon was significantly decreased (to 56% of control), resulting in an increase in maximum plasma concentrations ($C_{\max}$) and area under the concentration–time curve (AUC) of zaleplon [178]. In addition, it was discovered that the 5-oxo metabolite (M2) of zaleplon was formed at a reduced rate after cimetidine administration, implicating inhibition of AO as the culprit. Follow-up *in vitro* studies by Renwick [177] demonstrated that cimetidine does in fact inhibit AO-mediated formation of M2 in a competitive fashion, albeit weakly, in both human liver cytosol ($K_i = 155 \mu\text{M}$), and liver slices ($K_i = 506 \mu\text{M}$). Considering this lack of potency for inhibiting AO, it is unclear whether this is the true mechanism of the observed *in vivo* interaction between cimetidine and zaleplon. However, despite the limited impact demonstrated in humans to date, it is conceivable that clinical drug–drug interactions mediated by inhibition of AO may become more prevalent. For example, there appears to be a shift in the chemical matter toward more heterocyclic-containing drug candidates in effort to reduce lipophilicity and cytochrome P450-mediated metabolism, which may result in increased metabolic clearance by non-cytochrome P450 drug-metabolizing enzymes such as AO. This observation, coupled with a number of clinically used drugs being identified as inhibitors of AO, suggests that this particular mechanism of drug–drug interaction may become more relevant in the future. The parameter that will ultimately drive the magnitude of any clinical drug–drug interaction will be fraction metabolized by AO ($f_{\text{m,AO}}$). If the $f_{\text{m,AO}}$ for any drug is >0.5 , then the likelihood exists for some measurable (e.g., greater than equal to twofold) DDI in the clinic [179].

11.5.2 Inhibitors of XOR

11.5.2.1 In Vitro. Historically, there has been much less structural diversity among the known inhibitors of XOR, as the most effective inhibitors appear to be purine-based analogs. In addition, inhibition of XOR has been viewed as therapeutically beneficial, as it is involved in the biosynthesis of uric acid (Fig. 11.28). Allopurinol is the gold standard inhibitor of XOR, and is used therapeutically in the treatment of gout [180], a condition resulting from overproduction or underexcretion of uric acid and subsequent deposition of urate crystals in joints. Allopurinol has been characterized as a mechanism-based inhibitor of XO, whereby the product formed following hydroxylation at the 6-position (oxipurinol) complexes with the partially reduced MoCo, which prevents further electron transfer [181,182]. Xanthine oxidase enzymes may also be inactivated by cyanide, which works to remove the required sulfur atom from the molybdenum, making the enzyme catalytically inactive [183]. Arsenite also appears to be a general inhibitor of XOR and acts in a similar manner, which is an interaction with the critical sulfur atom at the molybdenum center [184]. Research into the mechanism of non-purine inhibitors has continued, with the recent report of a crystal structure of arsenite-inhibited XOR [185].

While allopurinol has been the treatment option of choice for patients suffering from gout for >30 years, a small percentage of the population suffers from adverse

Figure 11.28 Inhibitors of xanthine oxidase.

events, including hypersensitivity reactions, toxic epidermal necrolysis, liver dysfunction, and acute nephritis [186,187]. These clinical observations have triggered numerous efforts to design potent inhibitors of XO that may be used therapeutically without the deleterious side effects. For example, BOF-4272, a pyrazolo-triazene derivative (Fig. 11.28), was found to bind tightly to both the oxidized and reduced forms of XOR, likely in the xanthine-binding site [188], and thus, was expected to inhibit the enzyme for a longer duration than allopurinol *in vivo*. This longer duration of action was in fact demonstrated *in vivo* in rats [189]. Structure–activity relationship (SAR) studies of a series of 1-phenylpyrazoles was reported in 2001 [190], with a number of compounds displaying enhanced inhibitory potency on XOR compared to allopurinol. The strategy employed here was to introduce a phenyl group at the N-1 position of allopurinol to effectively block conversion to unnatural nucleotides, as well as replacement of the 4-hydroxypyrimidine moiety with a carboxylic acid to enhance coordination with molybdenum (Fig. 11.28). From this effort, Y-700 (1-(3-cyano-4-neopentyloxyphenyl)pyrazole-4-carboxylic acid) was discovered as a potent inhibitor of XOR ($IC_{50} = 5.8$ nM) that displayed long-lasting hypouricemic effect in a rat pharmacology model, with an ED_{20} of 0.55 mg/kg (0–6 h) and 1.4 mg/kg (0–24 h), both superior to allopurinol. Y-700 was subsequently dosed in humans where a single-oral dose (5, 20, or 80 mg) led to a dose-dependent reduction of serum uric acid levels [191]. Febuxostat, a structurally related non-purine selective inhibitor of XOR, was also found to be more potent ($K_i < 1$ nM) than allopurinol, selectively inhibiting both the oxidized and reduced form of XOR. In addition, febuxostat was more effective than allopurinol at lowering serum urate levels in patients [192], and was subsequently approved in February 2009 by the US Food and Drug Administration for the management of hyperuricemia in patients with gout (Uloric®). These few examples make it clear that a purine core is not obligatory for potent inhibition of XOR. The work to identify additional diverse inhibitors of XOR is extensive and extends beyond what we

are able to review here. For a more comprehensive summary of current XOR inhibitors, the reader is directed to a recent patent survey [193].

11.5.2.2 In Vivo Drug–Drug Interactions. Drug–drug interaction due to inhibition of XOR by allopurinol has been demonstrated *in vivo* with the anticancer agent 6-mercaptopurine (6-MP), which is metabolized by XOR to 8-hydroxy-6-MP, and then to thiouric acid [194]. When rhesus monkeys and humans were pretreated with allopurinol, peak plasma concentrations ($C_{\max}$) of 6-MP following oral dose were markedly increased, in the order of 400% in monkeys and a 500% in man [102]. Allopurinol pretreatment also led to a 300% increase in plasma AUC in monkeys after oral 6-MP and a 500% increase in AUC in man. However, allopurinol pretreatment had minimal effect on the disposition of intravenously dosed 6-MP. This observed difference was concluded to be the result of inhibition of first-pass metabolism of orally dosed 6-MP by allopurinol, consistent with the known tissue distribution of XOR in the liver and intestine [195].

11.6 DISTRIBUTION OF MOLYBDENUM-CONTAINING HYDROXYLASES IN HUMANS

Subcellular distribution of molybdenum-containing hydroxylases is thought to be mainly centralized to the cytosol of the cell [116,196,197]. Therefore, these classes of enzymes are aqueous soluble proteins, and when prepared from tissue, these enzymes are primarily found in the 100,000 *g* supernatant fraction. There have been claims that both AO and XOR have been found in the mitochondrial fraction of liver homogenates from two species, rat and guinea pig [198,199], although there are claims that the activity observed could not be repeated in subsequent experiments [126]. Interestingly, Critchley *et al.* [198] provided evidence that in guinea pig liver XOR has 52% higher level of activity ($\mu\text{mol}/\text{min}/\text{mg}$) in the mitochondria than that of the cytosol. It was also found that AO in the cytosol versus the mitochondrial fraction have different substrate specificities, thus indicating at least two different forms of AO specific for a particular subcellular site. In a XOR specific study using electron microscopy by Frederiks and Vreeling-Sindelarova identified XOR in the peroxisomes of hepatocytes, and in multiple organelles of Kupffer and sinusoidal cells [196], including the rough endoplasmic reticulum, lysosomes, and endocytic vesicles. Since there is still some controversy as to the subcellular localization of both AO and XOR, more work to affirm such claims may be necessary.

The expression levels of mammalian molybdenum-containing hydroxylases have been studied with many different techniques. The techniques include immunohistochemistry, cytochemistry, Western blot, Northern blot, RT-PCR, and *in situ* hybridization of mRNA. Each one of these techniques has its strengths and weaknesses as pointed out by Garattini *et al.* [1], and Beedham [200]. The main issues with these techniques for molybdenum-containing hydroxylases are (i) the structural similarity of all the enzymes and the specificity of the antibodies used to assess the specific protein, (ii) the measurement of mRNA does not necessarily translate into active protein, and this is especially true with molybdenum-containing hydroxylases because of the complex assembly of the enzymes. However, when all the data is compiled for XOR and then AO, the results are telling. Utilizing all of these techniques, the basis of what we

have learned about the tissue distribution of XOR first came from experimental data in nonhuman species [201–203]. When we compare species, the mammary glands and the intestine seem to have higher levels of XOR than the liver. Human and cat are the exceptions to the rule, where these two species have approximately equal amounts in the intestine and liver. In most species, the proximal portion of the small intestine has the highest XOR enzymatic activity, and when quantified, the epithelial lining of the duodenum and the jejunum is rich in both mRNA and XOR protein [201,202]. A similar such abundance is supported in humans because of high observed activity in both epithelial and goblet cells throughout the villi of the intestine [204], which seems to peak midway through the villi. It has also been reported that activity, protein and mRNA indicative of XOR gene expression, is high in the human liver [201,203,205], but in human lung, expression is barely detectable [206]. Additionally, there have been observations that XOR is present in plasma [207,208]. In lactating mammary gland, acinar cells show high XOR activity compared to nonlactating mammary gland [204]. It has also been reported in humans that a large proportion (>80%) of XOR enzyme in milk is not active [209]. There are conflicting reports of XOR expression in the heart and brain [24,210,211]. Interestingly, XOR activity is increased in tumor tissue in the brain [212] and decreased or absent in aggressive breast cancer [213] hepatomas (rats) [214], and colon tumors [215]. A summary of relative amount of human XOR in tissues can be found in Table 11.2.

AO in humans is abundant in the liver [216] but has also been found in the kidney, pancreas, prostate, testis, ovary, and especially the respiratory system [25,216,217]. AO has also been observed via immunostaining in the adrenal gland, cortex, and the zona reticularis. It has been reported that AO in both the liver and adrenal glands has similar abundance and is the richest source of AO mRNA transcript [218]. AO has also been found in the glial cells in the spinal cord but not in neurons [24]. A summary of relative amount of human AO in tissues can be found in Table 11.3. An interesting comparison analysis by Garattini and Terao [55] of AO mRNA expression of human tumor and the corresponding normal tissues indicated that normal tissues produce large amounts of AO mRNA, where the corresponding neoplastic tissue produce very little. This finding is most relevant and potentially most useful for targeted drug delivery in the case of both liver and lung cancers.

11.6.1 Distribution of Molybdenum-Containing Hydroxylases in Other Species

In rodents, the distribution of AOX1 and AOX3 are overlapping. The most abundant source of these two enzymes in adult rodents is the liver. It was found that the stage of development of the mouse influences when one or the other is expressed. AOX3 is expressed in newborn mice, where AOX1 does not appear in measurable quantities until the mouse is fully grown [29]. Localization of AO in the liver of rats has been observed via histological staining. The staining of the hepatic tissue provides evidence that the distribution of the activity is not homogeneous, and seen mostly in the pericentral and not the periportal area [219]. The second richest tissue containing AOX1 and AOX3 in mouse is the lung; this observation has also been indicated in rat [220]. According to Garattini and Terao [55], mouse AOX3 mRNA is only expressed in the testis, where in mouse and rhesus monkey AOX3L1 is only expressed in the nasal mucosa. AOX1 mRNA has been detected in mouse testis, heart, and the epithelial layer of the esophagus [221], although, no translated protein can be found in either the heart

or esophagus [221]. Interestingly, Kurosaki *et al.* [221] found that brain AO activity was much higher than what the levels of mRNA would have dictated, suggesting that the synthesis of the mouse AO is under translational and posttranslational control. Unique to only a few species, including rodent, but not human and chimpanzee, AOX4 protein is highly expressed at the Harderian gland, a specialized structure in the orbital cavity of the eye region [222]. These types of unique sources of AO may be of consequence when trying to extrapolate human pharmacokinetics from other species and using multiple AO substrates. A summary of AO species differences in tissues can be found in Table 11.3.

Moderate XOR activity has been found in mouse intestine and liver, although XOR mRNA was found at low levels in all tissues studied [203]. Only when subjected to interferon and induction of XOR was XOR mRNA found in mouse liver, intestine, kidney, heart, and lung.

Krenitsky *et al.* [223] when comparing liver and intestinal XOR activity utilizing xanthine as a substrate, found that rabbit XOR oxidase activity was lower than that of mouse, rat, or guinea pig, although, xanthine dehydrogenase activity in rabbit has been shown in heart, brain, and skeletal muscle [224]. When studying guinea pig crude extracts for AO and XOR activity, Beedham *et al.* [225] measured activity in the liver, lung, kidney, intestine, spleen, and heart. Two of the three substrates were specific for

AO (phenanthridine and phthalazine) and one was specific for XOR (xanthine). AO activity in guinea pig was observed highest in the liver, and for the kidney, the AO activity was ~40% of that observed in the liver. XOR activity was found highest in the small intestine, the jejunum, followed by the duodenum, ileum, liver, spleen, kidney, and lung. A summary of XOR species differences in tissues can be found in Table 11.2.

Unfortunately, studies on both dog and cat tissue-specific and cell-specific distributions are few, although, Terao *et al.* [56] have provided a substantial amount of AO and XOR distribution data for the dog in a single publication. It is reported that dogs are devoid of liver AO activity. Dogs, however, do express homologs of AO in very specific regions of the body. The expression of the AOX4 protein in dogs is found in the lacrimal gland, which is a functional substitute for the rodent Harderian gland. The other actively expressed AO protein, AOX3L1, is expressed similarly in the mouse and rhesus monkey, only in the nasal mucosa. On the other hand, dog XOR mRNA is ubiquitously expressed at low levels in multiple tissues [56].

11.7 XOR AND AO ACTIVITY VARIATION

Humans have a wide range of XOR activity, which spans >3.6-fold variation in enzyme activity [226]. Although the variation is substantial in humans when compared to other mammals, humans have low enzyme activity [227]. There are conflicting reports on the influence of gender on XOR activity [226,228]. Guercioli reports that males have higher XOR activity than females, while Relling reports the opposite. These studies were conducted quite differently, and may be influenced by study specific variables. Guercioli's study utilized cytosolic liver fractions from Caucasian patients, while

Relling's study measured caffeine metabolites in urine of both Caucasian and African-descent healthy volunteers. Unfortunately, Relling's reported results do not stratify by ethnicity and gender together to understand the impact of both at the same time. This stratification could potentially help explaining the different outcome on gender from the two studies.

Variation in active XOR has also been observed when comparing milk of different species. Abadeh *et al.* [209] found that although the expression levels were similar in both bovine and human milk, the human XOR activity for xanthine metabolism was 1–6% of that in bovine. It has been observed that a majority of this disparity can be attributed to two inactivated forms of XOR, either demolybdo-XOR or desulpho-XOR [209,229].

Early works by Krenitsky *et al.* [98,223] provided a unique insight in to the type of mammals that express high levels of AO and those which do not. In these works, it is noted that herbivores have extremely high levels of AO, where carnivores have low levels. It has been alluded that the high levels of AO in herbivores is because of certain dietary plants that might be rich in sources of AO substrates. Perhaps uniquely because of the omnivore status, humans and primates [230] possess some AOX1 activity in the liver.

Several works have displayed marked differences in AO activity within a single animal species, as well as between species [100,231], including some marked differences with famciclovir [104]. In an *in vitro* study conducted by Al-Samy *et al.*, variation of hepatic AO was observed utilizing two AO substrates, DACA and benzaldehyde. Differences in both the K_M and V_{max} was observed from 13 human individual cytosolic fractions from both males and females [232]. Clearance differences between donors ranged from 16.6-fold with DACA and 2.75-fold for benzaldehyde, which is similar to other reported human AO variation for benzaldehyde [233]. Another work has reported up to 50-fold variation for benzaldehyde human AO activity [234]. Additionally, work by Yerino *et al.* [235] presented at the 2007 International Symposium of the Study of Xenobiotic (ISSX) provides a look at 23 donor cytosolic fractions with two AO substrates, which is more than any other study in the literature [232–234]. When reanalyzing the data of phthalazine or *p*-vanillin in a histogram and applying the D'Agostino and Pearson omnibus normality test, the activities of the 23 donors suggests a Gaussian distribution (Fig. 11.29).

A larger cytosolic sample set would be a more appropriate measure of population distribution, but none is presently available. The granularity of a larger study would help the hypothesis that the source of this intraspecies variability is because of multiple polymorphic enzymes distributed throughout the population [59,236]. Recently, the development of a noninvasive method for determining AOX1 activity *in vivo* [237] has been employed in the understanding of developmental AO activity in rats and Japanese children [238,239]. In Japanese children and the adults that they were compared to, a considerable interindividual variation was observed with a fourfold range in activity in individuals greater than one year of age. This method could also be employed to understand the frequency of activity in large populations and distribution modality of polymorphic AO. One of the most revealing examples of the existence of a polymorphic AO enzyme, in a species which expresses AO, was a series of works by Itoh *et al.* [31,32,240] conducted in rats. This series of experiments provided some insight as to why intra- and interstrain differences in AO activity are observed, with little or no observable change in mRNA transcription. In the earliest of the works [31], multiple

Figure 11.29 Histogram of phthalazine oxidation from 23 donors. *Source:* The data was acquired from the work of Yerino *et al.* presented at the 2007 ISSX meeting [235].

point mutations were observed, which divided the Donryu rats into ultra metabolizers (UM), extensive metabolizers (EM), and poor metabolizers (PM). As previously described in Section 11.2.1, two mutations were identified as being important, G377A and C2604T, thus translating to amino acid changes of 110Gly-Ser and 852Ala-Val. The UMs and PMs were homozygous at all four positions, where the EMs were heterozygous. Therefore, UMs translate to the amino acid at location 110 being a glycine and an alanine at amino acid 852, which differs in PMs translating to a serine and a valine, respectively. The observed specific enzyme activity in the UMs versus the EMs was greater than twofold $V_{\max}$, and a 20- to 40-fold difference in clearance ($K_M/V_{\max}$) of the S-enantiomer of RS-8359 was observable in the EMs versus the PMs. This effect was thought to be due to a change at amino acid position 110, which is conserved among rat species. Since this nucleic acid is near the Fe-S center, and the change shifts the isoelectric point from pH 5 to 6.2 from EMs to PMs. It was thought that this change of isoelectric point may cause a conformational change of the AO. In a later study investigating interstrain difference in activity, Itoh *et al.* [240] observed that a lack of homodimerization of the enzyme was responsible for the reduced activity in-between strains of rat. Further work implicated that the same point mutations (G377A and C2604T) drive the dimerization process and effectively drives the activity [32].

Species differences are most definitely due, in part, to the expression and the differing distribution of species-specific isoforms. There are many examples of variability in AO-metabolized drugs in different species. For example, Zaleplon [108] had been reported to have marked species differences between monkey and rat. SGX523 shows acute renal failure in humans because of obstructive nephropathy from a particular poor soluble AO urinary metabolite, not seen in preclinical toxicology species. Diamond *et al.* conducted studies to understand the production of this poorly soluble metabolite in multiple species. The specific AO metabolite was formed in humans and monkeys and to a much lesser extent in rat and none in dog. Interestingly, several prodrugs of an antiviral agent, 9-(3-hydroxypropoxy)guanine, are even activated by different molybdenum-containing hydroxylases. In rats, XOR was the responsible

enzyme, where as AO catalyzed the reaction in humans [241]. Carbazeran, a successful inotropic agent in dogs, is another interesting example of AO species differences. It has been observed that carbazeran is extensively metabolized utilizing baboon and human liver cytosol *in vitro* but stable in dogs [91,92]. The phenomenon in dog is not specific just to carbazeran. Dog AO activity has been measured with a variety of substrates and found to be very low or absent [100,223,242]. Also of interest is the data suggesting that carbazeran metabolism is species specific. Both rabbit [243] and mouse (unpublished work, Fig. 11.30) show little or no AO-specific metabolism of carbazeran. In humans, baboons, marmosets, and guinea pig, affinity in the single digit

Figure 11.30 (a) Structures of carbazeran and zoniporide. (b) Unpublished results of a substrate depletion time course assessment of 1 μ M carbazeran (white) and zoniporide (gray), utilizing 2 mg/mL of mouse (no pattern) and human (diagonal lines) S-9 liver fraction in the presence and absence of 50 μ M hydralazine (a potent and specific AO inhibitor) [169,175] in 100 mM potassium phosphate buffer pH 7.4. Zoniporide [88] was assayed as a parent compound depletion positive control of both mouse and human AO. Maximum extrapolated half-life was 120 min. Y-axis displayed on the natural log scale for better visualization.

to 100 μM range with a moderate to very high V_{max} (20–150 mol/min/mg) is observed. The V_{max} for rat is much lower for carbazeran, which is similar to what is observed in the mouse (Fig. 11.30). This outcome may suggest that the rodent family may share the lack of activity with the rabbit.

11.7.1 Regulators and Inducers of Molybdenum-Containing Hydroxylases

XOR has a variety of mechanisms that govern its protein expression and level of enzymatic activity. One of the most studied is modulation by cytokines. Of the cytokines, interferon has been characterized by a number of laboratories [244–247]. The impact was shown via a mouse study using either an artificial increase in type I interferon or an interferon inducer such as bacterial lipopolysaccharide. A substantial induction of XOR was observed in multiple tissues in the mouse model [203]. In a complementary study using epithelial cells *in vitro*, a similar response was reproduced [244]. These studies suggest that this induction of XOR is a feedback mechanism to help mediate certain features of interferon activity. Studies inhibiting XOR activity do not support the involvement of XOR in influencing the therapeutic or detrimental effect of interferon [248].

In other examples of cytokines influencing XOR transcription, the proinflammatory cytokines, tumor necrosis factor α (TNF- α), interleukin-1, and interleukin-6 levels also increased XOR mRNA levels in human kidney epithelial cells [244,245]. Anti-inflammatory corticosteroids have also been found to induce XOR expression. This phenomenon is surprising, since both anti-inflammatory and proinflammatory cytokines induce XOR. Regardless, the induction triggered by both of these proinflammatory and anti-inflammatory cytokines suggests a potential XOR function in inflammation.

Other non-cytokine and exogenous stimuli are capable of inducing XOR as well. Linder [249] reports that oxygen tension has a significant effect on XOR expression, where hypoxia increases XOR, while hyperoxia tends to decrease the observed activity. It was noted that there are observations of both hypoxia and hyperoxia effecting XOR both on the transcriptional and posttranscriptional level, depending on the cell line studied and the species line was derived from. Both phorbol-12-myristate-13-acetate (PMA) and tetrachlorodibenzo-*p*-dioxin (TCDD) are inducers of XOR gene expression in many tissue types and animal species [250–256]. PMA has a questionable mechanism; it is unclear whether it directly induces or influences the production of inflammatory cytokine. Alternatively, TCDD is an environmental pollutant that induces XOR activity directly via activation of the TCDD receptor, or otherwise known as the *Ah receptor*. XOR induction derived from the TCDD receptor in the liver is suspected to be the reason for TCDD-induced liver damage. TCDD is thought to induce liver damage by the increased XOR expression and the coinciding increased production of superoxides.

Regulation of AOX has been proposed to be a consequence of multiple factors, both genetic and endogenous. Interindividual variability in AOX1 expression in humans has been suggested to be responsible for both methotrexate pharmacokinetic variations in the clinic [100]. Garattini and Steinberg [59,236] have posed that the variations seen in the methotrexate study maybe a consequence of allelic variants or polymorphic enzymes, which express a catalytically defective enzyme. Endogenous factors such as sexual steroid hormones have been shown to regulate gender-specific difference in AO levels in the liver of mice [221,257,258]. The mRNA of mouse AOX1 seems to

increase with levels of androgens, where as estrogen decreases the levels of AOX1 mRNA. This influence of androgens could be responsible for the observed difference in the non-preclinical species, the camel. A twofold increase in AO-specific activity in males opposed to female camels was observed using phenanthridine as a specific probe [259]. Another example is zebularine; when studied in cancer prone Apc(Min/+) mice, showed gender-specific expression which influenced its chemopreventive activity for intestinal polyposis [260,261]. In humans, *in vitro* and *in vivo* comparisons have taken place. The data suggests little if any gender-influenced AO activity differences. *In vitro* studies by Al-Salmy *et al.* [238] did not detect a relationship between gender and AO activity, which correlates with the aforementioned clinical study in Japanese children and adults. Additionally, with limited clinical data, penciclovir also shows little to no gender difference [262].

Exogenous compounds, such as the previously mentioned TCDD [263], as well as methanesulfonate [264], nitrosoureas [264], nitroguanidines [264], curcumin [265], and phenethyl isothiocyanate [266] have been demonstrated to induce AOX1.

11.7.2 Ontogenic Expression

No correlation has been associated with age and XOR enzyme activity, regardless of the method of analysis [226,228,267]. This also includes a study of allopurinol metabolism, which according to Turnheim *et al.* is a function of XOR activity. They observed that in elderly subjects compared to young controls, the clearance of allopurinol is unchanged. Others have reported that allopurinol is metabolized primarily by AO. If taken together, one could conclude that neither AO nor XOR vary in elderly subjects compared to younger controls. An AO-specific example is famciclovir, in which elderly subjects produced similar amount of the active metabolite penciclovir in urine as patients. This result is somewhat clouded because of the reduced renal clearance of penciclovir in the elderly [268,269]. There have been multiple studies looking at very early development stages in multiple species of both AO and XOR. In a rabbit study by Nichols *et al.*, a lack of AO variation across age groups and life events was observed. Their data indicated that hepatic tissue from nonpregnant, pregnant, fetal, and newborn rabbits did not differ significantly in its ability to reduce 2,6-dichloroindophenol in the presence of acetaldehyde substrate. In another study utilizing mice at various stages of development, Holmes [270] observed that up to three weeks from birth, no XOR was present, whereas AOX-1 could be detected in a 20-day-old fetus. There has been a single study in humans conducted comparing the relative amounts of nicotinamide and its metabolites in urine of young Japanese children and adults [238]. The study population consisted of 101 children, of both sexes ranging in age from shortly after birth to 10 years of age, and 26 adults. When relative urinary product values of the children were compared to the adults, it was found that AO activity rapidly increased in a linear fashion with age to adult levels within first 365 days of life. Also of interest was that AO activity of neonates was found to be ~10% of those observed in adults. No data were available for fetal AO activity, but the expectation is that the activity would not surpass those of neonates. It was suggested that since AO activity is immature in human neonates and infants, perhaps there is a need to make dose adjustments with drugs such as methotrexate and cyclophosphamide based on AO activity to avoid increase risk of side effects including leucopenia, thrombocytopenia, liver failure, renal

failure, and nephropathy [238]. Also, when all the species data is placed together, the data indicates that there is species-specific triggering of AO expression at certain stages of early life, although this phenomenon might be homolog influenced, thus also species specific.

11.7.3 Ethnic Differences

The activity of XOR in the human population appears to follow a normal Gaussian distribution [226,271,272], although marked variation in expression and activity has been observed in some ethnic populations. As previously mentioned in Section 11.7, Relling *et al.* measured caffeine metabolites as indicators of specific drug-metabolizing enzyme activities. Utilizing ratios of the metabolite (1-methyluric acid) to substrate (1-methylxanthine), a comparison of xanthine oxidase activity was made between Caucasians, subjects from African descent, males, and females. It was found that subjects from African descent and males, in general, have lower XOR activity. Interestingly, Relling identified that the lowest xanthine oxidase activities were observed in males from African descent, and that the highest activities were observed in the females of both ethnic groups, but stated that the distributions within each gender according to ethnic group are not bimodal. However, the author later stated, in a personal communication that compared the potential impact of environmental and iatrogenic influences, such as methotrexate, exercise, interferons, smoking, and other variables on xanthine oxidase activity, the impact of gender and ethnicity is unlikely to be substantial. As far as the authors are aware, this type of ethnic analysis has not been conducted with an AO-specific substrate.

11.8 *IN VITRO*–*IN VIVO* CORRELATION (IVIVC)

XOR has a narrow substrate pool compared to AO, and thus as far as the authors are aware, there has not been an attempt to perform an *in vitro*–*in vivo* correlation. In 2010, Zientek *et al.* [273] attempted an IVIVC for human AO. Eleven test compounds were assayed using two *in vitro* systems (pooled human liver cytosol and liver S-9 fractions) to calculate scaled unbound intrinsic clearance, and were then compared to calculated *in vivo* unbound intrinsic clearance, to examine if any correlation existed. The correlation offered a means by which newly synthesized compounds that are shown to be metabolized by AO can have a prediction made for whether it will have a high, medium, or low CL'_{int} (Fig. 11.31) in the clinic.

The *in vitro* system chosen, be it pooled human liver cytosol or S-9 fraction, can be calibrated using high, medium, and low CL'_{int} selected from the 11 described in Fig. 11.31. Then a CL'_{int} can be obtained for a new compound and measured in relation to the chosen controls. The authors suggest that compounds with AO-mediated CL'_{int} less than that of zaleplon would be predicted to be low CL'_{int} *in vivo* and compounds with CL'_{int} equal to or greater than 6-deoxypenciclovir, zonisporide, or *O*⁶-benzylguanine would be predicted to be high CL'_{int} . Thus, a relative scale has been provided that can be used for *in vitro*–*in vivo* correlation of AO clearance and can aid in directing drug discovery programs regarding when structural modifications are needed because of unacceptably high aldehyde-oxidase-mediated metabolism.

Figure 11.31 Bar graph calibrating *in vitro* scaled intrinsic clearance with *in vivo* free intrinsic clearance for 11 compounds metabolized by aldehyde oxidase in humans. Numbers in parentheses refer to estimated *in vivo* free intrinsic clearance. Bars are placed in the order of *in vivo* free intrinsic clearance (mL/min/kg). Source: Bar graph adapted from Zientek *et al.* [265].

11.9 CLINICAL IMPLICATIONS

From a drug attrition standpoint, AO appears to have substantially more impact on clinical programs than XOR. Interest in AO by the pharmaceutical industry has increased dramatically of late [2,55]. Several recent literature reports have demonstrated that extensive metabolism by AO has led to the ultimate termination of clinical candidates, either due to toxicological outcomes or due to higher-than-predicted clearance in humans, yielding unacceptable pharmacokinetic properties. In each of these cases, unexpected results were encountered in the clinic, likely because metabolism of these candidates was only evaluated in liver microsomes, which are devoid of AO activity, or predictions of human clearance were extrapolated from preclinical species (e.g., rat, dog) that possessed significantly lower AO activity relative to humans. Metabolically, despite both oxidative and reductive mechanisms catalyzed by AO, oxidation of heterocyclic ring systems appears to be the most relevant pathway for drugs that have met their demise in clinical studies (Table 11.4).

11.9.1 Carbazeran

Carbazeran was an inotropic drug developed in the early 1980s that was perhaps one of the first examples of a clinical candidate that fell victim to extensive AO-mediated metabolism [92]. In early pharmacological investigations in dog, it was observed that carbazeran demonstrated good oral bioavailability (62–74%), which lead to a favorable

TABLE 11.4 Summary of Drug Candidates that have Either been Discontinued Because of Poor Oral Exposure in Early Clinical Studies, had Human Clearance Values Underpredicted, or Demonstrated Toxicity Attributed to Aldehyde Oxidase Metabolism

Drug	Structures	Preclinical Data Package Used for Human PK Predictions	Clinical Outcome	References
Carbazeran		Dog PK	<5% F-Termination	91
Zaleplon		Liver microsomes, mouse, rat, and dog PK	Clearance underpredicted (1 h half-life)	274
BIBX1382		Liver microsomes, mouse, rat, and dog PK	5% F-Termination	275

RO1		Rat, dog, and monkey PK	0.7 h half-life—termination	276
SGX523		Liver microsomes, rat and dog PK	Obstructive nephropathy—Termination	23
FK3453		Liver microsomes, rat and dog PK	M4 metabolite exposure >> FK3453—Termination	78

The arrow indicates the major site of metabolism by aldehyde oxidase.

pharmacodynamic profile in that species. However, following oral dosing to humans up to 350 mg, plasma levels of carbazeran were essentially undetectable, with oral bioavailability <5%. The observed profound differences in pharmacokinetic profile in dog and human has been attributed to the lack of AO activity in dog, with the predominant metabolite in both baboon and human liver cytosol being the AO-derived 4-phthalazinone metabolite [91], which illustrates the extreme importance of understanding species differences in metabolism and identifying a species with AO activity that is representative of human.

11.9.2 Zaleplon

Zaleplon is a sedative hypnotic used mainly in the treatment of insomnia. Clinically, the clearance of zaleplon was underpredicted roughly sixfold, which resulted in a short half-life in humans of 1 h [274]. It was later published that one of the predominant metabolites of zaleplon was 5-oxo zaleplon, confirmed to be AO derived by both chemical inhibition studies, and incubations conducted in the presence of $H_2^{18}O$ [165]. As it turns out, development of this drug was actually not discontinued since the short half-life actually provides advantages for a sleep aid.

11.9.3 BIBX1382

BIBX1382 was a drug candidate being evaluated clinically as an inhibitor of epidermal growth factor receptor (EGFR) for the treatment of cancer. In human liver microsomes, it was observed that BIBX1382 was mainly metabolized by CYP2D6, and in preclinical pharmacokinetic evaluations in rat and mice, oral bioavailability ranged between 50% and 100%. Following oral dosing to human patients, plasma levels were far below that expected to be efficacious (~5% oral bioavailability), and a previously uncharacterized metabolite was observed in the urine of one patient, that was also circulating in human plasma at high concentrations [275]. Retrospective experiments by Dittrich *et al.* also confirmed that BIBX1382 was metabolized by hepatic AO, and that the rhesus monkey appeared to be a suitable surrogate for human AO metabolism.

11.9.4 RO1

The pharmacokinetics of a novel p38 MAP kinase inhibitor was evaluated in six healthy male subjects following a 50-mg oral dose. Surprisingly, the observed terminal mean half-life was only 0.7 h, even though a half-life of 5.9 h had been predicted using common allometric scaling approaches based on pharmacokinetic data from rats, dogs, and monkeys [276]. The major drug metabolite of RO1 (M1) represented 220% of the AUC of parent drug, and was shown to be generated by AO.

11.9.5 SGX523

Extensive metabolism by AO may not only result in poor pharmacokinetic properties but also toxicity. SGX523 was a clinical candidate for an oncology target (c-MET, a receptor tyrosine kinase) that progressed because of favorable potency and selectivity profile for the target, as well as a comparable metabolite profile in liver microsomes from rat, dog, monkey, and humans. Thus, conventional drug safety studies were

conducted in rats and dogs to enable first-in-human (FIH) studies. However, following doses administered to human subjects of >80 mg, acute renal failure was observed [23]. Interestingly, metabolite profiling of human plasma indicated a major metabolite that was not observed *in vitro* in liver microsomes. Retrospective analysis by Diamond *et al.* demonstrated a major NADPH-independent metabolite (M11, 2-quinolinone-SGX523) when SGX523 was incubated with liver S-9 fraction, which was subsequently shown to be generated by AO. In addition, male cynomolgus monkey was shown to generate the M11 AO metabolite in substantial quantities *in vitro*, and safety studies were thus conducted in this species, where the adverse renal effects were reproduced. The ultimate cause of the renal toxicity was deemed to be the M11 metabolite that crystallized in the kidney because of poor solubility. This represents a great example of not just considering pharmacokinetic outcomes, but also toxicity outcomes, highlighting the critical importance of identifying an appropriate toxicology species with a comparable metabolite profile to humans.

11.9.6 FK3453

The most recent example of poor oral exposure in humans that was not predicted is FK3453, a novel adenosine A1/2 dual inhibitor being evaluated in Japan for the treatment of Parkinson's disease. While FK3453 underwent minimal cytochrome P450-mediated metabolism *in vitro* and demonstrated favorable preclinical pharmacokinetic properties in rat and dog, the development of this compound was discontinued because of extremely low oral exposure in humans [78]. It was again found that the poor oral exposure was the result of extensive metabolism by AO.

In summary, when one considers the first example of carbazeran failing in the clinic because of extensive AO-mediated metabolism, which is a time spanning over 25 years, it suggests that first principles in biotransformation are not being followed consistently. Understanding the complete metabolism of drug candidates, and not just the metabolism in human liver microsomes, is crucial. As medicinal chemists have successfully optimized small molecules via chemical modification to have less cytochrome P450-mediated metabolism, other drug-metabolizing enzymes such as AO may begin to play a larger role in drug biotransformation. Thus, a renewed focus by drug metabolism scientists on these types of non-P450 metabolic pathways should become standard practice. These standard practices, as suggested by Pryde *et al.*, should include evaluating metabolism in cofactor-supplemented liver S-9 fraction or isolated hepatocytes [2].

11.10 FUTURE PERSPECTIVES

Since molybdenum-containing hydroxylases are a complex enzyme family, and what is known about these enzymes is in its infancy compared to that of the cytochrome P450s and perhaps uridine 5'-diphospho-glucuronosyltransferase, much work is needed to put in perspective the implications of metabolism for this class of enzyme. As the science of molybdenum-containing hydroxylases in humans and preclinical species matures by building on the foundation of the current knowledge, it will become easier to relate these enzymes in drug research. There are active efforts underway to solidify chemical structure–activity relationships, and once better understood will become a

larger part of drug design. These structural advancements will provide scientists with the understanding as to the diversity of metabolic reactions and mitigation or minimization of molybdenum-containing hydroxylase metabolism. Tools such as specific inhibitors will provide ways to elucidate the contribution of such enzymes, once universally accepted enzyme abundance values has been achieved. From the literature, there have been efforts to understand the enzyme variability in population and the reasons why. This is an area where it is believed will benefit from more intensive research. Taken together, structural understanding, contribution to metabolism, and population variability will place this enzyme family in perspective compared to, and in addition to other drug-metabolizing enzymes.

12.1 SUMMARY

In the drug and foreign compound metabolism literature, amine oxidation and carbon oxidation reactions are well documented for the reactions of the FAD-containing monooxygenase [1] and the cytochrome P450s [2]. However, there are many other enzyme systems that are capable of catalyzing these reactions. This review provides an overview of the various amine oxidases, such as the copper-containing amine oxidases (CAOs) and flavin-containing amine oxidases. The copper-containing enzymes also have a prosthetic group formed from a tyrosyl residue in a self-catalyzed oxidation reaction with copper. There are four different prosthetic groups that can be formed from tyrosine or tryptophan and that are critical for the various catalytically important reactions of these related proteins. The flavin-containing amine oxidases play important roles in the metabolism of neurogenic amines, D- and L-amino acids and polyamines. However, they metabolize exogenous compounds as well. A second set of enzymes are involved in the reduction of azo and nitro compounds, mainly involving bacterial and mammalian flavoproteins and the cytochrome P450s. These enzyme systems also reduce quinones, halogenated compounds, hydroperoxides, and α , β -unsaturated aldehydes. This chapter describes the biochemical and molecular details of these genes

and their gene products, with an eye to identifying tools that would be valuable in establishing which might be involved in oxidative and reductive metabolism of new molecular entities synthesized for drug therapy.

12.2 INTRODUCTION

Among the many reactions involved in the metabolism of drugs and foreign compounds, the amine oxidation and reduction reactions are mechanistically the least well documented in the literature [2]. This is due in part to the common use of a single isolated cell types or tissue fractions (microsomes, nuclei, mitochondria, or cytosol) to study foreign compound metabolism in academe and industry. Amine oxidation and reduction often are missed unless intact cells or tissue are used and a careful tissue fractionation study is performed with any new compound of interest [3]. Often, this is due to two different enzyme systems contributing to the activity observed in the same tissue fractions/cell or the second enzyme system existing in an organelle other than the microsomal fraction. Thus, such studies result in an underestimation of the role of these interesting enzymes in the metabolism of nitrogen-containing organic compounds. For example, in our early studies on hydrazine metabolism, we discovered an enzyme activity in the mitochondrial fraction of rat liver that oxidized procarbazine, a 1, 2-disubstituted hydrazine, to its azo derivative [4]. We performed careful subcellular fractionation of rat liver to demonstrate the organelle the enzyme activity was associated with (i.e., microsomes or mitochondria) and further characterized the biochemical nature of the mitochondrial activity. After the use of monoamine oxidase (MAO) inhibitors and partial purification following kynuramine deamination activity, we determined that the enzyme responsible for this activity was mitochondrial MAO. We also demonstrated that procarbazine was a competitive substrate with kynuramine. While cytochrome P450 can oxidize nitrogenous compounds such as primary and secondary amines and hydrazines [5–7], other enzyme systems also oxidize these compounds to *N*-hydroxy or azo compounds. Many of these are the MAOs and diamine oxidases (DAOs) that are discussed in this chapter.

The reduction reactions of azo and nitro compounds are reactions that also have been shown to be catalyzed by cytochrome P450s and other electron-transfer proteins, such as NADPH:cytochrome P450 reductase and NAD(P)H:quinone oxidoreductase. These reactions are also underappreciated and can account for reduction of azo, nitro, and α , β -unsaturated alkene compounds, such as neoprotosil, nitrofur, and 4-hydroxynonenal, respectively. The work of Levine and Lu [8] demonstrated that specific cytochrome P450s, such as CYP4A and CYP3A4, account for the major catalysts for azo reduction in microsomal fractions from liver and intestine, in addition to flavoproteins, such as NADPH:cytochrome P450 oxidoreductase (POR).

12.3 AMINE OXIDASES

There are two classes of amine oxidases, those that use covalently bound quinones and copper as cofactors and those that use a prosthetic flavin group for catalysis. In general, they catalyze the same chemical reaction, namely, oxidative deamination leading to formation of an aldehyde, ammonia, and hydrogen peroxide (Eq. 12.1). All

three products formed are chemically reactive and specific enzymes are required to dispose of the reactive products formed.

Both classes display bi-bi ping-pong kinetics, which implies that two half reactions are involved in amine oxidation (Eqs. 12.2–12.4). The oxidant is an enzyme-bound prosthetic group that undergoes cyclic reduction/oxidation reactions and varies with each class of amine oxidase. An aldimine intermediate is formed in the oxidation step, but it is chemically unstable and decomposes to ammonia and the aldehyde product (Eq. 12.2). The following section describes the characteristics of these two classes of amine oxidases and the prosthetic groups involved in amine oxidation.

12.3.1 Copper-Containing Amine Oxidases (CAOs)

The CAOs were the first quinoproteins discovered and their characteristics were described by Hauge [9] and Antony and Zatman [10,11] in the early 1960s for the bacterial enzymes glucose dehydrogenase and methanol dehydrogenase. However, the identity of the cofactor involved was not defined for some years and Anthony and Zatman [10] suggested it was a pteridine derivative. These proteins contain a covalently bound quinone formed from a tyrosine or tryptophan residue, which serves as an electrophilic group to covalently bind amines or alcohols, before their oxidation by a metal redox center, yielding hydrogen peroxide as a product. Through the study of bacteria and lower eukaryotes, a role for CAOs in the degradation of amines as a source of energy and basic nutrients was deduced. The presence of CAOs in mammalian tissues suggests that there may be other important roles for these enzymes. There are four known mammalian genes (*AOC1–4*) that are described in detail below. The cofactor for the bacterial enzymes was shown to be a pyrroloquinolone quinone (PPQ) by Salisbury *et al.* [12] and Knowles *et al.* [13], whose studies were based on the earlier work of Duine and coworkers [14]. No examples were known for such novel quinone cofactors in mammalian enzymes until the 1990s, when Hartmann and Klinman [15] suggested a quinone cofactor for bovine plasma copper-amine oxidase, first assumed to be PPQ. Since that time, a number of mammalian enzyme systems involved in amine oxidation have been described and a variety of quinone cofactors have been elucidated. These CAO quinoproteins are divided into four basic forms containing different posttranslationally modified tyrosine or tryptophan residues capable of enhancing the catalysis of oxidative metabolism of primary amines [16]. The four types of side chain-derived quinone cofactor groups that are formed

in eukaryotic organisms use posttranslational, self-driven oxidation of a tyrosine within a highly conserved sequence [Ser/Thr-X aa-X aa-Asn/Tyr (topoquinone (TPQ))-Asp/Glu-Tyr/Asn] to yield a peptide-bound 2,4,5-trihydroxy-phenyl-alanine quinone (TPQ) residue that is the critical catalytic prosthetic group on the enzyme for amine oxidation [17–19]. A second enzyme class consists of proteins containing a lysyl tyrosylquinone (LTQ) prosthetic group [20]. These oxidases have prosthetic groups that involve two critical amino acid residues, lysine and tyrosine, resulting in the formal adduction of the lysine residue to a TPQ intermediate similar to that deduced for bovine serum amine oxidase. The other oxidases have been shown to contain tryptophan-derived quinone cofactor quinoproteins [21–23], where cysteine tryptophanquinone (CTQ) and tryptophan tryptophylquinone (TTQ) residues are covalently linked to form a complex structure (Fig. 12.1).

The formation of the known quino-cofactors requires several steps, starting with copper-catalyzed hydroxylation of either tyrosine or tryptophan residues within a relatively conserved amino acid sequence to yield an *ortho*-quinone ring. The mechanism for the formation of these quinones has been studied with the purified *Hansenula polymorpha* amine oxidase by Klinman and coworkers [17,19]. In the case of TPQ in plasma amine oxidase, no further modification of the tyrosyl quinone occurs for productive catalysis. The unconjugated quinone carbonyl group at the para position allows for Schiff base formation with nucleophilic monoamine or adduction by other

Figure 12.1 Quinone cofactors of various copper-containing amine oxidases as described by DuBois and Klinman [16]. TPQ, 2,4,5-trihydroxy-phenyl-alanine quinone; LTQ, lysine tyrosylquinone; CTQ, cysteine tryptophylquinone; TTQ, tryptophan tryptophylquinone. *Source:* Modified from DuBois JL, Klinman JP. Arch Biochem Biophys 2005;433:255–265., with permission from Elsevier Inc.

inhibitory nitrogenous compounds, such as phenylhydrazine, semicarbazide, clonidine, and phenylethylhydrazine. The other quinoproteins have products of oxidized tyrosyl or tryptophyl rings cross-linked with other nucleophilic amino acid side chain residue, such as lysine, cysteine, or tryptophan. For CTQ, TTQ, and LTQ, the end products are oxidized tyrosyl or tryptophyl residues that are further cross-linked with another nucleophilic amino acid side chain residue, namely, tryptophan, lysine, or cysteine. This cross-linking process may provide a unique function for the proteins, forming a relatively stable cross-link [lysyl oxidase (LOX)], modifying the redox potential of the cofactor to enhance reactivity, protecting the reactive cofactor from side reactions, and/or reducing movement of the cofactor at the active site [24]. Further examples of such quinoproteins and the study of their reactions are needed to define the unique properties of these complex proteins. With that description of quinoproteins, we describe several classes of enzymes whose function might affect the study of drug metabolism, leading to new metabolic products not expected from the cytochrome P450s or FAD-containing monooxygenase.

12.3.1.1 Diamine Oxidase (DAO). The DAOs are a group of enzymes that display substrate specificity for oxidation of diamines, such as histamine [25]. DAO is expressed in the placenta, kidney, gut, lung, and brain. In the intestine and kidney epithelial cells, DAO is released from basolateral vesicles at the plasma membrane in response to heparin and is subsequently cleared from the plasma. The IUB nomenclature designation for DAO is EC 1.4.3.22 classifying it as an amine:oxygen oxidoreductase (deaminating) (copper) enzyme, and it is encoded by the *AOC1* gene found in nearly all mammalian species. The human enzyme appears to have a subunit molecular weight of 70–105 kDa and contains one atom each of copper and magnesium [26,27]. Histamine and 1-methyl-histamine are excellent substrates. A human intolerance syndrome in pregnancy has linked high circulating levels of histidine to decreased levels of plasma DAO [25]. Other substrates described for the human enzyme are spermine, spermidine, acylated putrescine, cadaverine, and related compounds, for example, [8-arginine]vasopressin, [8-lysine]vasopressin, collagen, and tropocollagen. Although DAO has been shown to have some activity toward monoamines, it displays little or no activity toward higher substituted amines. The pH optima of the human enzymes are in the range of 9–10, but other forms have been shown to have other pH optima.

Like the amine oxidases described below, DAOs contain copper and 2,4,5-trihydroxy-phenyl-alanine quinone. In a copper-deficient state in mammals, this enzyme activity may be diminished like the amine oxidases because it easily loses or gains copper depending on the concentration of free copper in the cell [25]. Because DAO contains TPQ and therefore a reactive carbonyl group, they are inhibited by carbonyl-specific reagents such as semicarbazide or phenylhydrazine. The enzyme also has been shown to be inhibited by drugs such as isoniazide (tuberculostatic agent), cimetidine (histamine H₂ receptor agonist), clonidine (antihypertension drug), and several antiprotozoal agents (pentamidine and berenil). 2-Hydrazinopyridine and benzylamine are inhibitors, as they are for the other CAO enzymes, because of the presence of the active carbonyl functional group of TPQ cofactor utilized in the deamination reaction.

12.3.1.2 Retina-Specific Amine Oxidase (RAO or Lysyl Oxidase, LOX). There are four LOX genes in humans (LOXL1, LOXL2, LOXL3, and LOXL4), and their full

comparison has not been fully documented to date. They are believed to be involved in the development of many tissues and also in invasive processes during cancer metastasis [28,29]. A retina-specific amine oxidase (RAO), described by Imamura *et al.* [30] as LOX, is composed of 729 amino acids giving a molecular weight of 80.6 kDa. It is encoded by the *AOC2* gene. Its IUB nomenclature designation is EC 1.4.3.13, and its substrates are collagen and elastin in the extracellular matrix (ECM) of ocular tissues. It is synthesized as a glycosylated proenzyme with molecular weight 50 kDa per subunit and is converted to its active form (molecular weight, 32 kDa) by procollagen C proteinase (bone morphogenic protein-1) before secretion to the ECM of the eye. The disparity in molecular weight may be due to the fact that it is a secreted protein and that it is heavily N- and O-glycosylated, leading to aberrant migration on SDS polyacrylamide gel electrophoresis [31]. Reports of multiple LOX isoforms can be found in the literature [31]. It is ~62.2% related in sequence to the bovine amine oxidase described by Janes *et al.* [18], and the active site is highly conserved among the amine oxidases. Imamura *et al.* [30] also demonstrated that this gene is expressed only in the eye, suggesting an important function of RAO in this tissue. Subsequent studies by Coral *et al.* [32] characterized a LOX enzyme in ocular tissues and suggested that proliferative diabetic retinopathy (PDR) and rhegmatogenous retinal detachment (RRD) result from ECM remodeling due possibly to improper collagen cross-linking. They demonstrated that LOX enzyme activity is significantly lower in the vitreous of PDR or RRD patients, relative to control subjects. This observation supports the report of Hewitt *et al.* [33] who provided a strong correlation between expression of a LOX variant in the ECM of individuals and the development of pseudoexfoliation syndrome, a condition in which the ECM appears to be aberrant and there is accumulation of abnormal fibrillar material in the anterior segment of the eye. They suggested that this syndrome may predispose humans to a glaucomatous optic neuropathy.

The roles of LOX in development and disease are numerous, as shown by the interest in its role in cancer metastasis, as well as normal tissue development [34]. It is known that strong nucleophiles (lathyrogenic agents), including nitriles, hydrazides, hydrazines, and ureides, cause defects in formation of connective tissues in developing animals. Agents such as β -aminopropionitrile, 2-chloroethylamine, and 2-bromoethylamine are also potent inhibitors of cancer cell metastasis, demonstrating the chemical nature of the quinoprotein. The critical function of LOX in processing collagen and elastin to complete the posttranslational processing of these molecules and its association with disease and defective connective tissue development provide a potentially unique future therapeutic target for future investigation.

12.3.1.3 Semicarbazide-Sensitive Amine Oxidase (SSAO). Semicarbazide-sensitive amine oxidase [SSAO; EC 1.4.3.6; (amine:oxygen oxidoreductase (deaminating) (copper-containing))] is a glycosylated dimeric copper-containing enzyme mostly bound to outer membranes of smooth muscle cells, endothelial cells, and adipocytes; it has been described as a vascular ectoenzyme [35–37] since it appears to be a secreted protein with full enzyme activity. This protein is encoded by the *AOC3* gene. It was initially discovered as a benzylamine oxidase activity found in cultured porcine aortic smooth muscle cells and smooth muscle cell homogenates [38–40]. The enzyme's activity is also present in other tissues, such as uterus, ureter, and vas deferens. Research characterizing the toxicity of allylamine on myocardium and other vascular tissues suggested that SSAO is responsible for the oxidative metabolism to

acrolein, the toxic intermediate responsible for tissue damage. The toxicity toward the myocardium was prevented by administration of hydralazine, a hydrazine-containing drug [41–44], which now can be explained by its adduction to the reactive carbonyl of the quinone cofactor. The unique toxicity of allylamine reported in the literature led Boor and coworkers to characterize the protein by following its semicarbazine-sensitive benzylamine oxidizing enzyme activity. Boor and coworkers [45,46] demonstrated that swine aortic smooth muscle cell homogenates or cultured smooth muscle cells could oxidize allylamine to acrolein and lead to the view that acrolein most likely is the toxic agent causing the deleterious effects of allylamine on myocardial and vascular dysfunction. The purified protein was shown to be a homodimer with each monomer displaying a molecular weight of 90–100 kDa when isolated from either bovine lung or swine aortic smooth muscle cells [42,45,47]. From the primary sequence of the bovine lung enzyme, it contains 762 amino acids to provide a molecular weight of 84.8 kDa. The first 16 amino acids of its N-terminus possibly represent a signal peptide involved in synthesis and secretion. The extracellular portion of SSAO is apparently cleaved to generate a soluble enzyme that circulates in the plasma [42,44], explaining why Boor and coworkers [45,46] could isolate the enzyme from the media taken from cultures of swine aortic smooth muscle cells. Although the protein was identified as a secreted extracellular protein, cell fractionation showed that the majority of intracellular SSAO activity is membrane bound with the principal intracellular site of localization in the microsomal fraction that also contain the golgi apparatus that participates in the secretion process. Careful fractionation of plasma membranes also provided evidence that SSAO is predominantly localized in the plasma membrane of rat and aorta smooth muscle cells, likely facing away from the cell membrane where it can encounter its substrates [35,42]. Since it can be found in the media during culture of swine aorta smooth muscle cells [46,48], it appears that it can be processed to a soluble form as discovered by Boor's group.

In addition to benzylamine and allylamine, circulating amines such as methylamine, 2-phenylethylamine, aminoacetone, histamine, tyramine, tryptamine, and protein-bound amines appear to be substrates for SSAO [35]. The substrate specificity varies depending on the species studied. As predicted by the reaction it catalyzes (Eqs. 12.2 and 12.3), it displays a ping-pong catalytic mechanism. A unique feature of the enzyme is that it binds copper tightly relative to the DAO and plasma amine oxidase (PAO) [35,46]. As its name implies, it is inhibited by strong nucleophiles, including semicarbazine, amiloride, hydralazine, phenelzine, and phenylhydrazine.

SSAO has been shown to be identical to vascular adhesion protein-1 (VAP-1) that is induced during inflammation and mediates interaction between lymphocytes and endothelium [49]. The tissue distribution of VAP-1 is similar to SSAO and is responsible for inducing lymphocytic cell adhesion and granulocyte extravasation [50]. Ongoing research in vascular biology suggests that baseline VAP-1/SSAO activity can be used as a predictor of hemorrhage after tissue plasminogen activator (tPA) treatment. Since semicarbazide and other compounds, such as hydralazine, ameliorate VAP-1/SSAO activity, it is proposed that anti-VAP-1/SSAO drugs given with tPA may prevent neurological disorders following with ischemic stroke [51].

12.3.1.4 Plasma Amine Oxidase. The plasma amine oxidases are the best studied mammalian CAO, as exemplified by the extensive research done by a number of groups and the seminal work of Klinman and her collaborators in identifying the cofactor [16].

Among the early publications on the plasma amine oxidases was a report by Mason and coworkers [52] demonstrating that this enzyme contains copper in its active state; the enzyme also has been suggested to contain zinc, which is essential for its activity. Yet a number of studies using electron paramagnetic resonance could not detect a redox change in the Cu(II) center during catalysis [53]. Blaschko and coworkers [54] also demonstrated the essential role of copper by administering a diet deficient in copper and measuring the resulting enzyme activity of the plasma. As a copper enzyme, its bluish color can be observed during the later steps of the purification process. In addition, Blaschko *et al.* [54] suggested the enzyme contained pyridoxyl phosphate because of its absorbance at around 440 nm, a common characteristic of the TPQ that can be followed spectrophotometrically during the course of self-catalysis of the native protein to the active posttranslational modified enzyme. Subsequently, several groups [13,54] documented that the purified enzyme did not contain pyridoxal phosphate, but on the basis of NMR spectra suggested that it contained PPQ. At the time Klinman began her studies on plasma amine oxidase, she referred to PPQ as the cofactor in her 1987 publication using reductive trapping of substrate/inhibitor to the bovine plasma amine oxidase [15]. Subsequently, she deduced that the cofactor was not PPQ, but a new quinone cofactor, TPQ. Her group also established the oxidative mechanism by which the tyrosyl residue was converted to the TPQ cofactor [17–19, 54].

Plasma amine oxidases are listed with the IUB nomenclature EC 1.4.3.21 as being amine:oxygen oxidoreductase (deaminating) (copper-containing). It is encoded by the CAO4 gene (*AOC4*) in humans [44]. These enzymes have been purified and characterized from several species (bovine, humans, swine, and pea seedlings); they share many properties in common. The PAOs display native molecular weights of 180 kDa and are composed of two subunits (70–90 kDa) accounting for the presence of two copper (II) molecules and two active carbonyl groups per mole of enzyme, the latter being susceptible to adduction with amines and hydrazines. Three critical histidine residues are proposed to be available for the binding of copper, and early work using zinc to displace copper demonstrated that this protein can easily be made replete of copper. This observation also provides an explanation for reduced levels of PAO in plasma during dietary depletion of copper [44,52,55]. Although benzylamine and methylamine have been the major substrates used in studies of this enzyme, there are reports that the natural substrates for this class of enzymes are physiologically active amines, such as spermidine and spermine, catecholamines, and tryptamine derivatives. Other amines such as tyramine have been shown to be oxidized but with low affinity, and tryptamine, epinephrine, serotonin, or agmatine do not appear to be substrates [52,55]. The pH optima for the reactions varies depending on the substrate in use; for example, for spermine, the pH optimum is 6.2, while for spermidine it is 7.2 [56].

AOC4 is known to be expressed in mammalian liver, with the encoded protein being a secreted protein, leading to the high levels seen in bovine and porcine blood. In humans and rodents, there are much lower levels of this activity in plasma, although these species all have an *AOC4*-related gene. In these species, *AOC4* exhibits a single base change that converts the codon 255 (tryptophan) to a stop codon, yielding a nonfunctional, truncated protein [44]. In humans, the mRNA can be detected in the liver, and splice variants of the gene have been reported [57]. In the mouse and rat, only fragments of the *AOC4* gene exist.

Since the enzyme is a quinoprotein, strong nucleophiles, such as aryl- and alkylhydrazines, and other nitrogenous compounds inhibit oxidation by forming hydrazide or

semicarbazide forms of the cofactor. Clonidine, an antihypertensive that binds to α_2 receptors, is an inhibitor that changes the orientation of the TPQ relative to copper, yielding an inactive cofactor–metal complex [58]. Adduction by these compounds to TPQ prevents the nucleophilic attack by the amine substrate as the first catalytic step, as shown by Klinman and DuBois [16] for phenylhydrazine.

12.3.1.5 Summary of CAOs. Since these CAOs have K_{cat} values equal to or greater than those of the cytochrome P450s, drugs and foreign compounds that contain a primary amine or that can be converted to a primary amine can be oxidatively deaminated to aldehyde metabolites. These aldehydes, such as acrolein in the case of allylamine, can cause toxicity, particularly if they are generated near sensitive target organs and have been proposed to result in aberrant cell signaling [59]. In addition, if primary amines contain an amino group that is a good nucleophile, but are not CAO substrates, they can serve as competitive inhibitors altering the disposition of other substrates. These properties allow the CAOs to be part of a drug–drug interaction mechanism that should be considered where warranted during drug development.

The CAOs are affected by dietary depletion of body stores of copper, and therefore, copper-deficient patients might experience difficulties with certain drugs or compounds that are CAO substrates, as has been seen with histamine-sensitivity syndrome seen during pregnancy. To date, relatively few studies exist related to the study of CAO regulation or limits on the self-driven posttranslational modification to form an active enzyme. Therefore, when amine compounds are a focus of study, one should be aware that CAOs are clearly involved in amine metabolism and are also critical for defined steps in collagen processing and connective tissue formation.

12.3.2 Flavin-Containing Amine Oxidases

A number of flavin-containing amine oxidases exist that rely solely on a flavin prosthetic group as the oxidizing cofactor in their catalytic mechanism (Eq. 12.2). These enzymes are distinctly different from the microsomal FAD-containing monooxygenases first described by Ziegler and Poulsen [1]. Owing to the role of flavin-containing amine oxidases in the metabolism of monoamines and D- and L-amino acids, they have been extensively studied and are defined as being amine:oxygen oxidoreductase (deaminating) enzymes with an IUB EC 1.4.3 designation. The enzyme family consists of several subclasses depending on their subcellular localization and amine substrate preferences. They are distinguished as MAOs, DAO, and polyamine oxidases. Because there is considerable sequence identity among these oxidase enzymes, it is presumed that they have similar molecular structures. In addition, there are multiple enzyme forms within each subfamily as seen below. The catalyzed reactions are a subset of the reactions as shown in Equations 12.1–12.4, except a flavin, such as FAD or flavin mononucleotide (FMN), is used as the prosthetic group. The first products formed in their reaction is reduced flavin and an aldimine intermediate (Eq. 12.5) that subsequently hydrolyzes to form an aldehyde and ammonium ion (Eq. 12.6). Molecular oxygen is the terminal oxidant for most reduced flavoproteins of this group (Eq. 12.7).

12.3.2.1 Monoamine Oxidase A (MAO A and MAO B). The MAOs are flavin-dependent oxygenases catalyzing the same basic reaction as the copper-containing quinoprotein class of enzymes (Eq. 12.1). A review article by Shih *et al.* [60] provides an overview of the MAOs and has an extensive reference list addressing the characteristics of the two enzyme forms (A and B) that are classified as EC 1.4.3.4 enzymes [61]. Their molecular weights deduced from their amino acid sequences are 59.7 and 58.0 kDa [62], respectively, and they have 70% amino acid sequence identity. MAO A and B are encoded by separate genes located on the X chromosome. They are membrane-bound enzymes found in the outer mitochondrial membrane in the brain and many other tissues, including liver and kidney [63]. Their cofactors are covalently linked FAD molecules, with a cysteine thiol linkage to the 8a position of the isoalloxazine ring [64]. The best studied substrates include dopamine, noradrenaline, 5-hydroxytryptamine, and tyramine (MAO A substrates), while benzylamine and 2-phenylethylhydrazine are preferred substrates for MAO B [60,65]. Excessive intake of tyramine, an MAO A substrate has been associated with the “cheese” reaction, in which processing of tyramine is inhibited by MAO inhibitors, leading to hypertensive crises. Clearance of some foodstuffs high in tyramine or other vasoactive amines is now known to be dependent on the MAOs, and their routine clearance is affected by the MAO inhibitors [39,66]. MAO B also oxidizes 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to its toxic metabolite. Production of this metabolite apparently is involved in the selective destruction of nigrostriatal neurons, resulting in a Parkinson-like disorder [67]. There are also form-specific inhibitors that allow differential inhibition in experimental studies, namely, clorgyline (MAO A specific) and deprenyl and pargyline (MAO B specific). Some species-specific differences in substrate specificity and inhibitor sensitivity are seen between the two enzymes.

In addition to amines, Coomes and Prough [4] demonstrated that MAO can oxidize monoalkyl- and 1,2-disubstituted hydrazines to form diazene and azo metabolites, respectively [68]. In the case of the monosubstituted hydrazines, the diazene intermediates are potent electrophiles capable of protein or nucleic acid binding, while the azo metabolites of 1,2-dimethylhydrazine and procarbazine (a 1-methyl-2-benzylhydrazine derivative) are stable but can be further oxidized to azoxy metabolites that are mutagenic [68]. Erikson and Prough [69] demonstrated that MAO catalyzed the oxidative metabolism of procarbazine, 1,2-dimethylhydrazine, *n*-propylhydrazine, and iproniazid. In the case of procarbazine, both clorgyline and propargyline were inhibitors of MAO A- and MAO B-catalyzed oxidation to azoprocabazine. Although endogenous amine metabolism by MAOs has been extensively studied because of their role in clearance of neuroamines, their metabolism of exogenous amines has been less well characterized.

12.3.2.2 D-Amino Acid Oxidases (DAAO). The pig kidney D-amino acid oxidase (DAAO) was one of the earliest flavoprotein oxidases discovered. This enzyme [EC 1.4.3.3, L-amino-acid:oxygen oxidoreductase (deaminating)] is a dimeric protein, with a subunit molecular weight of 38 kDa and containing a molecule of FAD per subunit [70]. DAAO principally is localized in the peroxisomal compartment of the pig kidney and is closely related to D-aspartic acid oxidases, comprising a small family of proteins with similar function. DAAO metabolizes most D-amino acids containing a single carboxylic acid group, from D-alanine to D-tryptophan, while D-aspartic acid oxidases metabolize dicarboxylic amino acids. The enzymes require substrates with both an amino and carboxylic acid group to achieve high levels of oxidative metabolism, and

the keto acids of the amino acids formed during oxidative metabolism by this enzyme are product inhibitors of the reaction. Since D-amino acids cannot be used for protein synthesis, the existence of DAAO in kidney lysosomes is believed to be critical for the disposition of D-amino acids.

12.3.2.3 L-Amino Acid Oxidases (LAAO). The substrate specificity for L-amino acid oxidase (LAAO), L-amino-acid:oxygen oxidoreductase (deaminating), EC 1.4.3.2, includes the L-amino acids, namely, alanine, aspartate, methionine, valine, leucine, isoleucine, tyrosine, phenylalanine, and tryptophan. Similar to DAAO, the keto acid metabolites of these amino acids are also inhibitors of this enzyme system. The enzyme purified from rat kidney was shown to have a subunit molecular weight of 49.3 kDa determined by flavin content, and on the basis of this molecular weight and the amount of flavin associated with the protein, is consistent with two FAD molecules per molecule of enzyme [71]. It has been assumed that this enzyme allows the clearance of L-amino acids that accumulate in the kidney because of excessive protein catabolism and release from various tissues before excretion. In murine lymphocytes, this enzyme was shown to have a molecular weight of ~90 kDa, suggesting its existence as a dimer in this cell type [72]. The enzyme's function in lymphocytes has been suggested to be antigen processing in lysosomes. During the development of drugs, namely, levodopa and carbodopa, that protect against excessive dopamine metabolism in brain, researchers were concerned that LAAO might be involved in the metabolism of dopamine and therefore may be a drug target for inhibition or inactivation. Other LAAOs in nature have been purified from venoms of various vipers, that is, *Calloselasma rhodostoma*, *Naja naja kaouthia*, and *Ophiophagus hannah*. These enzymes have similar properties to those characterized in mammalian species.

12.3.2.4 Polyamine Oxidases. Another member of the flavin amine oxidase family are enzymes that oxidize polyamines (EC 1.5.3.11). These enzymes are highly conserved among humans, mice, and rats and act on the acetylated products of spermine and spermidine, namely, *N*¹-acetylspermine and *N*¹-acetylspermidine, to produce spermidine and putrescine as products. *N*¹, *N*¹²-diacetylspermine, formed by acetylation of spermine via spermidine/spermine *N*¹-acetyltransferase, is also a substrate for the enzyme. The molecular weight of the polyamine oxidases is 61.8 kDa, and they contain FAD as the prosthetic group [73,74]. These enzymes are believed to be critical in maintaining polyamine levels in cells, although in at least some cells, the coupling of the polyamine transporter, SLC3A2, to the spermidine/spermine *N*¹-acetyltransferase suggests an equally important mechanism to control intracellular polyamine levels [75].

12.4 AZO REDUCTASES

Another set of reactions that have not been as well characterized as the dealkylation or ring hydroxylation reactions of cytochrome P450 are the azo, nitro, and other reduction reactions [2]. The azo reduction reactions have been of interest to pharmacologists and toxicologists for some time because of their effect on the azo dye industry, which produces azo dyes that are largely used for cloth coloration or as pharmaceutical agents for preventing bacterial contamination. In his 1991 review, Levine [76] described the role of azo dyes in carcinogenesis and mutagenesis and also addressed reductive

Figure 12.2 Steps of azo compound reduction to hydrazine and primary amines, including the putative reoxidation of radical intermediates by molecular oxygen. Hydrazine compounds have also been shown to be oxidized by cytochrome P450s, copper-containing amine oxidases, and monoamine oxidases [4–7].

metabolism in bacterial and mammalian cells. The oxidative metabolism of azo dyes includes N-dealkylation, aromatic ring hydroxylation, and N-hydroxylation to form azoxy derivatives, which have been extensively studied [68,77,78]. All these reactions tend to be catalyzed by the cytochrome P450s, and in the case of procarbazine, the oxidation of this 1,2-dialkylhydrazines to the azoxy derivatives leads to formation of a reactive methyldiazonium ion that probably accounts for the alkylation potential of this anticancer drug [7,79]. Azo functional group reduction occurs in the absence of molecular oxygen, and depending on the azo compound in question, reduction can occur in the presence of molecular oxygen. Since cytochrome P450 requires molecular oxygen for oxidation of C- and N-centers, only the reduction reaction can occur in the absence of oxygen. The reaction steps for azo reduction are shown in Fig. 12.2.

This review focuses on the unique azo reduction reactions catalyzed by mammalian liver microsomes and some bacterial systems. Interest in azo reduction was increased after the unique work of Bovet and others [80,81], who elucidated the need for reductive bioactivation of the antibacterial azo dye protosil, which on reduction yields sulfanilamide in rabbits. This is a classic prodrug reductive activation process. Other azo compounds were subsequently developed as effective antibacterial agents, but often, their azo linkage was not reduced, leading to excretion through a glucuronidation pathway. Miller and Miller [82] who studied the metabolic activation of butter yellow (*N,N*-dimethylaminoazobenzene) also demonstrated that NADPH in the presence of liver microsomes and oxygen could not only sustain the demethylation of this azo dye but also reduce it to *N,N*-dimethyl-*p*-phenylene-diamine [77,78]. The chemical properties of various azo dyes appear to dictate how easily they are reduced; these properties are addressed in the following sections as well. In addition to the cytochrome P450s, other enzymes play a role in azo dye reduction, principally flavoproteins.

12.4.1 Flavoproteins

As mentioned by Levine in his 1991 review [76], many azo dyes used in agricultural or clinical applications are taken orally, and only a small fraction of the parent compound is excreted in the urine with the azo linkage intact, suggesting that reductive metabolism is a major route of disposition. If administered by routes other than per os, substantial biliary excretion of the intact dye can be observed in experimental animals. The lack of reduced azo compound in bile suggests that if azo reduction occurs, the metabolites are rapidly oxidized back to the azo compound in liver or that the gut microflora may be significantly involved in disposition of azo dyes. Their uptake is dependent on solubility because those with charged groups, such as sulfonates, are apparently not well absorbed. More lipid-soluble dyes, such as dimethylaminoazobenzene, were shown

by the Millers [77,78] to be extensively metabolized by both oxidative and reductive metabolism when administered by intraperitoneal injection. Their work demonstrated step-wise N-demethylation and ring hydroxylation reactions leading to products that are excreted into the bile as glucuronides, while reduction to stable products such as amine compounds leads to urinary elimination.

Walker published a review on azo compound metabolism in 1970 [83] and summarized for the first time the understanding of azo dye metabolism. Several important points were made in this review, including the fact that several groups had shown that water-soluble azo dyes were mostly reduced in the gut, based on the pronounced effects of antibiotics. Ryan and Wright [84] used the dye tartrazine, which was not reduced by liver extracts in the presence of NADPH. When added to cell-free extracts of *Proteus vulgaris*, several azo dyes were shown to be rapidly reduced, supporting the view that bacterial cells can reduce azo dyes. In subsequent work, Ryan and coworkers [85] showed that a number of bacterial isolates of differing origin can reduce azo dyes, and thereby, they established that gut bacteria are an important source of reduction in rodents and probably humans. At this time, others were purifying the bacterial NAD(P)H-dependent reductases and several enzymes were shown to reduce a number of dyes [86,87]. The bacterial flavoproteins normally do not bind FAD or FMN as tightly as the mammalian flavoproteins do, so the addition of FAD or FMN was required to optimize the azo reduction reaction.

Hernandez *et al.* [88,89] noted that purified lipase-solubilized NADPH:POR catalyzed the anaerobic reduction of the azo compound neoprotosil to sulfanilamide. Using inhibitors of the oxidoreductase, the microsomal azo reductase activity was concordantly inhibited with the activity of the purified enzyme. Studies at the NIH by Gillette's group also addressed nitro reduction reactions, and the group found that these reactions were stimulated by the addition of FAD. Similar experiments with exogenous FAD were performed by Walker [83], where he noted that if FAD was added to liver microsomal fractions, the azo reductase activity increased. The apparent azo substrate specificity approximates first-order kinetics, because of the slow step of reduction being the reaction of reduced flavin with the dye. Many bacterial flavoproteins have since been isolated and nearly all reduce azo and nitro compounds, suggesting that this reaction is a nonphysiological reaction of nearly all flavoproteins [86,87,90]. These reactions most likely account for the metabolism of azo dyes in the intestine (Eqs. 12.8–12.10), although flavin-independent reactions can occur with bacterial enzyme systems by direct reduction with reduced pyridine nucleotides [91]. However, many of these flavoprotein-catalyzed reductions are oxygen sensitive and the reduction reactions are normally only seen during anaerobic metabolism, depending on the dye substrate's chemical properties (electrochemical potential, etc.).

12.4.2 Cytochrome P450

The studies of Mueller and Miller [77,78] were among the first to address the possibility of cytochrome P450 serving as the reducing enzyme for azo reduction. Masters

et al. [92,93] had shown that steapsin, a pancreatic lipase preparation from pigs, could release a cytochrome *c* reductase enzyme activity from liver microsomes. Masters' group subsequently purified the membrane-bound form of the flavoprotein [94], which retains its azo reductase activity (Masters BSS, Prough RA, unpublished research). Their subsequent work demonstrated that the enzyme released by lipase treatment was a proteolytic form of the NADPH:POR. Hernandez *et al.* [88,89] used the method of Masters *et al.* [92] to purify the oxidoreductase to homogeneity and demonstrate that the pure enzyme could reduce neoprontosil under anaerobic conditions. When Hernandez *et al.* [88,89] utilized steapsin to release the oxidoreductase from the microsomal membrane, they noted that azo reductase activity was decreased to 25% of control, but NADPH:cytochrome *c* reductase activity actually increased 20%; neotetrazolium dye reduction to formazin also increased slightly. They also noted that on induction of cytochrome P450 in liver microsomes by 3-methylcholanthrene, the microsomal azo reductase activity increased without a concordant increase in reductase activity, suggesting that the polycyclic aromatic hydrocarbon inducible cytochrome P450s (the CYP1 family) were azo reductases. When they used phenobarbital as an inducing agent, both cytochrome P450 and oxidoreductase levels were induced. Subsequently, they used carbon monoxide as an inhibitor of cytochrome P450-dependent reactions and noted that CO decreased microsomal azo reductase activity by 30–40% with liver microsomes from control, 3-methylcholanthrene- or phenobarbital-treated rats. The azo reductase activity of purified oxidoreductase was unaffected by replacing the air atmosphere with CO. Hernandez *et al.* [88,89] proposed that there were two enzyme systems that resulted in anaerobic reduction of neoprontosil, the first was the NADPH:POR itself and the other system was cytochrome P450, which itself requires two-electron transfer from the oxidoreductase to maintain its catalytic process (Fig. 12.2).

The subsequent work of Levine *et al.* [76,95,96] addressed several points about azo dye reduction; first, which cytochrome P450s catalyze azo reduction and second, why some azo dyes required anaerobiosis for reduction by these systems and others do not. In their studies, they identified two types of azo dye substrates related to 4-dimethylaminoazobenzene, those substrates whose reduction was sensitive to O₂ and CO and those that were insensitive [95,97]. A common chemical feature of the two classes was that the insensitive class tended to have electron-donating ring substituents such as -OH, -NH₂, -NH-CH₃, or -N(CH₃)₂ group. The sensitive class of substrates contained electron-withdrawing groups, such as -SO₃H, -COOH, -COOCH₃, and -AsO₃H₂. They also noted that cyanide ion potentially inhibited the reduction of the O₂-insensitive azo dye substrates, suggesting that the insensitivity/sensitivity may be a property of the ferrous cytochrome P450 [98]. Azide did not differentially affect the azo reduction of their set of compounds. One explanation for the differences in O₂/CO sensitivity was that the hydrazine intermediates (Fig. 12.2) may have differential sensitivity to reoxidation by molecular oxygen to the azo intermediate or alternatively be reduced to the primary amine metabolite. On the basis of the work from our groups, we know that hydrazines are easily oxidized by cytochrome P450s and are also sensitive to metal-catalyzed oxidation [68,99]. The mechanism accounting for the oxygen sensitivity or insensitivity remains unsolved.

Pursuing the approach of Hernandez *et al.* [88,89], Levine demonstrated that induction of liver microsomal enzymes from animals treated with various chemicals greatly affected azo dye reduction and each condition displayed a different substrate specificity for azo dyes [100]. Induction by clofibrate increased azo dye reductase activity

for nearly all dyes, suggesting a role for the CYP4 family of cytochrome P450s in azo dye reduction, while phenobarbital, pregnenolone-16 α -carbonitrile, and isosafrole were all inducers of azo dye reduction for *O*-methyl red [8,100]. Their results demonstrated that members of the CYP1, CYP2, CYP3, and CYP4 families all reduce azo dyes under anaerobic conditions and depending on the structure of the azo dye, possibly under aerobic conditions. Mallett *et al.* [101,102] utilized purified NADPH:POR and CYP2B1 to reconstitute the anaerobic reduction of the azo dye amaranth, an oxygen-sensitive reaction. In addition, they added FMN and FAD to yield higher rates of reduction of the dye. In the absence of FMN, amaranth reduction was dependent on oxidoreductase, CYP2B1, and dilauroylphosphatidylcholine; in the presence of FMN, the oxidoreductase appeared to be the source of reduction. They proposed two mechanisms of reduction for amaranth: direct reduction by oxidoreductase that was stimulated by addition of FAD and cytochrome P450-mediated reduction in the absence of FAD. Clearly, CO-insensitive azo reduction reactions are apparently unaffected by flavin deficiency, while the flavoprotein-dependent azo reduction reactions are heavily affected by depletion of flavin *in vivo* or supplementation of flavin *in vitro* [103].

Milton *et al.* [104] demonstrated that clofibrate was a potent inducer of CYP4A1 in rat liver and defined several inhibitors of the enzyme, including saturated fatty acids and clofibrate. Raza and Levine [105,106] demonstrated that azo dyes were most effectively reduced in liver microsomes from ciprofibrate-treated rats. In addition, they demonstrated that addition of *N,N*-dimethyl-4-aminoazobenzene to reaction mixtures containing liver microsomes from clofibrate-treated rats inhibited lauric acid hydroxylation and that lauric acid inhibited *N,N*-dimethyl-4-aminoazobenzene reduction with these same microsomal fractions. Their work also demonstrated that a CYP4A-specific inhibitor, 10-undecynoic acid, inactivates laurate hydroxylation, but not azo reductase activity, suggesting that the active site for oxidative metabolism is affected by the inhibitor for laurate oxidation, but not that for azo dye reduction. In addition, they reconstituted NADPH:POR with purified CYP4A1 to demonstrate that *N,N*-dimethyl-4-aminoazobenzene azoreduction is catalyzed by this enzyme in the absence or presence of oxygen, but in the presence of oxidoreductase alone, the flavoprotein could only reduce it under anaerobic conditions. Finally, they noted that in the reconstituted system, inclusion of FAD greatly enhanced azo reduction; the oxidoreductase alone was nearly as effective in reducing azo dyes in the presence of FAD than the reconstituted system. Lu and Levine [8] performed a more detailed study that demonstrated that azo reduction by cytochrome P450 is a two-electron process yielding the stable hydrazine (two-electron) or amine (four-electron) reduction product, while the oxidoreductase apparently only catalyzes one-electron reduction to an intermediate that is rapidly oxidized to the azo derivative.

Walker [83] and Levine [76] discussed the one- and two-electron reduction processes involved in azo dye reduction, arguing that those that are oxygen-insensitive must form stable two-electron reduced products like the hydrazine derivative, while oxygen-sensitive processes may catalyze one-electron reduction to a radical. It is known that molybdopterin-containing enzymes [76], such as aldehyde and xanthine oxidase, also reduce azo dyes but are sensitive to cytochrome P450 inhibitors, such as SKF-525A and metyrapone. These complex redox centers have common properties to the cytochrome P450s that make defining specific inhibitors difficult. However, one should consider whether any reduction reactions are noted to be oxygen/CO sensitive when studying

new molecules that are reduced, as well as the relative sensitivity to cyanide and azide ions to characterize various reactions.

12.5 NITRO REDUCTASES

Similar studies have been performed with nitro compounds, and among the early works, Gillette's group at the NIH documented that anaerobic nitro reduction of *p*-nitrobenzoate was catalyzed by liver microsomal protein in the presence of NADPH [107,108]. Carbon monoxide atmosphere caused an 80–90% inhibition of nitro reduction. In addition, they studied the formation of aniline from nitrobenzene, nitrosobenzene, and phenylhydroxylamine, noting that nitrosobenzene and phenylhydroxylamine were rapidly converted to aniline in a CO-sensitive reaction. The oxygen sensitivity of aniline production from any of the proposed metabolites reported in the literature suggests that anaerobiosis is required for net reduction due to the ease of oxidation of the substrate and intermediates by oxygen. On the basis of their studies, they described a reaction that required four 1-electron reduction steps (Fig. 12.3).

Other groups studied the role of NADPH:POR in these processes. For example, Delaforge *et al.* [109] demonstrated that trinitroglycerin is also reduced to eventually allow liberation of nitric oxide. Aristolochic acid is a nutraceutical found in evergreen and deciduous woody vines and herbaceous perennials of *Aristolochia* and *Asarum* of the Aristolochiaceae plant subfamily and is a naturally occurring nephrotoxic nitro compound. On reductive bioactivation, it forms DNA adducts in rodent tissues *in vivo* [110]. Bioreductive activation of the 6-nitro group of aristolochic acid by members of the CYP1A family has been proposed by Stiborova *et al.* [110] as the bioreductive activation mechanism of this chemical. Reduction of the nitro group leads to formation of a putative nitrenium intermediate and its subsequent reaction with nucleic acid bases results in formation of DNA and protein adducts.

Harada and Omura [111] provided mechanistic details about nitro reduction by demonstrating that inhibitory antibodies to NADPH:POR and several cytochrome P450s inhibited anaerobic reduction of *p*-nitrobenzene, but not antibodies against NADH:cytochrome *b*₅ oxidoreductase or cytochrome *b*₅. They also reconstituted the purified oxidoreductase and cytochrome P450s to document that the latter were required for the final step of reduction of phenylhydroxylamine to aniline, while the oxidoreductase could catalyze reduction of nitrobenzene and nitrosobenzene alone in the presence of NADPH. Moreno *et al.* [112] utilized electron spin resonance (ESR) to study trapped radical species formed during *p*-nitrobenzene reduction. They observed that under aerobic conditions, the major radical trapped was superoxide

Figure 12.3 Steps of nitro reduction to nitrosoamine, hydroxylamine, and primary amine derivatives, including the putative reoxidation of radical intermediates by molecular oxygen. Hydroxylamine compounds have been shown to be oxidized to nitroso derivatives by cytochrome P450s [6].

anion radical. At low oxygen concentrations, the putative radical species undergo intramolecular electron transfer and rearrange to form carbon-centered nitrobenzyl radicals that could also be measured by ESR. Radical trapping was not inhibited by CO or the nitrogenous cytochrome P450 inhibitor metyrapone. Radical formation for *m*-nitrobenzyl anion radical did not achieve a steady-state concentration, unless metyrapone or CO was included in the reaction mixture. This observation suggests that the POR is a major source of reduction [113,114], and this oxidoreductase-dependent reaction is increased by inclusion of cytochrome P450 inhibitors.

The study of other nitro compounds, 4-nitroquinoline *N*-oxide and 4-hydroxylaminoquinoline *N*-oxide, strongly supports the role proposed for the oxidoreductase in their reduction [115]. Furthermore, the studies suggest that this reaction is due largely to one-electron reducing flavoproteins such as POR since two-electron-donating flavoproteins, such as NAD(P)H:quinone oxidoreductase, do not generate superoxide anion radical. However, POR can reduce the one-electron reduced nitro compounds further, unless molecular oxygen is present to oxidize the radical species [114]. Many bacterial flavoproteins in the gut also catalyze these reactions and may protect mammals from nitro compounds taken in the diet. Bacterial and mammalian flavoproteins appear to be particularly effective in catalyzing reduction of nitro compounds, and the role of cytochrome P450s is perhaps less important for these compounds.

12.6 OTHER ENZYME-CATALYZED REDUCTION REACTIONS

A number of other reports of substrates being reduced by flavoproteins and possibly by cytochrome P450s have been reported. These have not been studied in depth, and anecdotes of such reports are included in the discussion below.

12.6.1 Quinones

Quinones have long been known to be reduced by most flavoproteins. The studies of Masters *et al.* [92] show that POR reduces cytochrome *c*, menadione, and 2,6-dichlorophenol indophenol. Our laboratories [116–118] also have studied the reduction of *t*-butylquinone by both POR and NAD(P)H:quinone oxidoreductase, suggesting that benzocyclic, naphthocyclic, and complex polycyclic aromatic hydrocarbon quinones are good electron acceptors for the flavoproteins. POR serves as a one-electron reducing flavoprotein, while NAD(P)H:quinone oxidoreductase serves as a two-electron reducing flavoprotein. In the case of one-electron reduced semiquinone radicals, they rapidly react with molecular oxygen to generate superoxide anion radical, but two-electron reduced hydroquinones react more slowly with molecular oxygen in the presence of metal catalysts [116,119]. A consequence for this difference is that one attains higher levels of quinone reduction by two-electron reduction because less radical quinone intermediate is available for reoxidation by molecular oxygen (Fig. 12.4). For the purpose of this review, we address only information known about reactions catalyzed by cytochrome P450s.

Capdevila *et al.* [120] used spectroscopic methods to study quinone reduction and reoxidation of benzo[*a*]pyrene-3,6-quinone as a model quinone. Reduction and reoxidation could be monitored at 480 nm (wavelength maxima for B[*a*]P-3,6-quinone). The quinone was observed to be rapidly reduced by liver microsomal fractions. The

Figure 12.4 Reduction of quinones by the flavoproteins, NADPH:cytochrome P450 oxidoreductase (POR), or NAD(P)H:quinone oxidoreductase. Semiquinone radicals reoxidize rapidly in the presence of molecular oxygen to yield the parent quinone and superoxide anion radical, while hydroquinones react less well with molecular oxygen [119].

reoxidation process was coupled to molecular oxygen reduction and hydrogen peroxide formation. The initial rates of oxidation were inhibited by anti-POR globulin and the nitrogenous ligand, metyrapone. Of interest, anaerobiosis or CO had no effect on the initial rates of reduction, only reoxidation was prevented. During steady state of the reaction, the quinone exists largely as the hydroquinone, but the level of reduction increases under anaerobic conditions, suggesting a redox cycling phenomenon similar to that seen with azo dyes and nitro compounds under aerobic conditions. This reaction was partially supported by purified POR but was not inhibited by metyrapone or CO [120]. The reoxidation reaction indicated that insufficient reduction occurred to attain full steady-state reduction of the quinone as seen with NAD(P)H:quinone oxidoreductase, known to catalyze two-electron reduction of menadione and *t*-butylquinone. Alternatively, the B[a]P quinone may be further metabolized by oxidative metabolism forming more polar metabolites. With benzyl- and naphthylquinones, total reduction of menadione and *t*-butylquinone can be achieved with purified NAD(P)H:quinone oxidoreductase, but not with purified POR [119,120]. These studies suggested one-electron reduction processes are involved in reduction involving both POR and cytochrome P450s, but not NAD(P)H:quinone oxidoreductase (Fig. 12.4). Complete reduction was never achieved in the presence of oxygen with either flavoprotein because of the slow comproportionation equilibrium of the quinone/hydroquinone couple (Eq. 12.11).

Vermeulen and coworkers [121,122] also noted that 2,3,5,6-tetramethylbenzoquinone (TMQ) was reduced to a one-electron reduced quinone in the presence of CYP2B. This reaction was apparently inhibited by SKF-525A, another nitrogenous ligand inhibitor of cytochrome P450. In a reconstituted enzyme system of POR and cytochrome P450, they followed the reduction of TMQ by ESR and noted that the semiquinone radical was produced at a higher rate when cytochrome P450 was reconstituted with POR than POR did itself. Cytochrome P450 inhibitors and inhibitory antibodies also were effective in inhibiting TMQ reduction. They concluded that reconstitution of TMQ reduction by POR with increasing concentrations of cytochrome P450 was correlated with the level of the hemoprotein in the reactions, thereby proving the role of cytochrome P450 as a reductive catalyst. Subsequent work

from this group on adriamycin and mitomycin C documented roles for P450 2B1 in one-electron reduction of these quinone compounds and their bioactivation by this process [122–124].

12.6.2 Reductive Dechlorination

Guengerich [2,125,126] has provided a number of examples from the literature for reductive dechlorination reactions. Other reviews have also summarized these reduction reactions [127,128]. The best studied dechlorination reactions are those monitoring metabolism of carbon tetrachloride [129] and halothane under anaerobic conditions [130–132]. These reduction reactions principally form reduced products in which the halide group is replaced by hydrogen or by the formation of olefins (Fig. 12.5). In each case, cytochrome P450 provides an electron to the parent halide compound from its ferrous iron species, liberating a halide ion and a carbon-centered radical. The chemistry of the radical appears to determine the product formed. For example, the products can react with molecular oxygen to form an oxidized product, as seen with the trichloromethane radical produced from CCl_4 radical. Interaction with molecular oxygen allows production of phosgene. Alternatively, loss of a second halide ion from the radical allows formation of an olefin, as seen during the reduction of halothane. Both reactions led to the formation of reactive intermediates capable of forming adducts with nucleophiles such as protein and nucleic acid bases [130–132]. As pointed out by Guengerich [2], Castro and Castro [133] proposed a consistent mechanism for reductive dehalogenation reactions (Fig. 12.5).

12.6.3 Reduction of Hydroperoxides

Hydroperoxides are also reduced by cytochrome P450s to yield alcohol and water (Eq. 12.12), as discussed by Guengerich [2]. The mechanism of this reaction is not fully appreciated since organic hydroperoxides apparently function as alternate donors of an atom of oxygen to ferric cytochrome P450 to form a perferryl species, a reaction similar to the key step in the P450 catalytic cycle involved in heterolytic cleavage of molecular oxygen [134]. Many examples of these hydroperoxide reduction reactions exist in the literature for the prostaglandin synthetases, lipoxygenases, and cytochrome P450s, in which a lipid hydroperoxide is reduced to a lipid alcohol [135]. Cytochrome P450s can not only produce lipid peroxides during the course of catalysis but can

Figure 12.5 Steps of reductive dehalogenation reactions: (a) molecular oxygen reacts with a radical (halide) to lose halogen [133] and (b) reductive dehalogenation forms olefins [129].

also convert such intermediates to the hydroxyeicosenoic acid as part of their catalytic mechanism.

12.6.4 α,β -Unsaturated Aldehydes

Recently, we have studied the metabolism of α,β -unsaturated aldehydes derived from lipid peroxidation, such as 4-hydroxy-2-nonenal and acrolein, using primary hepatocytes and expressed cytochrome P450s. We have shown that many cytochrome P450s catalyze the oxidative metabolism in an NADPH- and O_2 -dependent manner [136]. Specific cytochrome P450s of the CYP3A, 2B, and 2C families were effective in oxidizing aldehydes to their carboxylic acid. In recent studies [137], we also have detected a reaction in which the 4-hydroxy-2-nonenal is reduced to 4-hydroxy-2-nonenol in the presence or absence of oxygen. The reaction was not affected by replacing the normal air atmosphere with carbon monoxide or addition of inhibitors, such as metyrapone, to block the reaction. The α,β -unsaturated bond in aldehydes may allow reduction of these aldehydes to their alcohols, much like the oxygen-insensitive azo reduction reactions. This precedent suggests that there may be other reduction reactions of olefinic compounds by cytochrome P450s, and the tools for the study described by Levine and others may be important approaches to characterize these reactions.

12.6.5 Summary of Cytochrome P450 Reduction Reactions

Except for our report of 4-hydroxynonenal reduction, no cytochrome P450-dependent reduction reactions for endogenous compounds are known. As pointed out by Guengerich in his 2001 review [2], it is peculiar that this heme protein catalyzes reduction reactions at all because of the high reactivity of the hemoprotein in its ferrous form with molecular oxygen. The scientific community assumes that all ferric cytochrome P450s bind oxygen and subsequently the molecular oxygen is rapidly reduced. In tissues with low oxygen tension, reduction reactions might be favored [138]. Because the oxidation–reduction potential for ferric cytochrome P450s is around -300 mV , in the absence or presence of substrate, this species of cytochrome P450 should be an excellent one-electron reductant. Further study of the chemical mechanism of the cytochrome P450s is needed to address this anomaly. However, discovery of a reduced metabolite might direct one to assume either a flavoprotein or cytochrome P450 may be involved in these reactions.

12.7 CONCLUSIONS/FURTHER PERSPECTIVES

In the past, considerable attention has been directed toward the role of cytochrome P450 and FAD-containing oxygenase in amine oxidation reactions. However, an increasing number of studies in the literature require researchers to rediscover the role of the quinone- and flavin-dependent amine oxidases. This chapter attempts to describe the enzyme systems that can catalyze these reactions and provides examples of the reactions with exogenous compounds that have been shown to involve these enzymes. In addition, this chapter addresses the rare reduction reactions of flavoproteins and the

cytochrome P450s as a guide to the reader for considering rare reactions that occur in drug metabolism. The study of metabolic enzymes has been extensive, but it is clear there is much to be learned about these proteins on a single gene/protein level. Because bioreductive reactions for foreign compounds are rare, the authors hope that this review has provided a road map to assist in identification of such systems.

13.1 SUMMARY

Epoxides are three-membered carbon–oxygen compounds that typically arise from the metabolism of endogenous and xenobiotic compounds via chemical and enzymatic oxidation processes. Many different oxygenase enzymes are capable of forming epoxide derivatives, from either arene or alkene substrate; however, the cytochrome P450 monooxygenases are principal contributors to their generation. Certain epoxides are highly electrophilic and chemically reactive, and they have been implicated as initiators of various cellular toxicities, including the formation of DNA mutations and ultimately, cancers. Therefore, it is of vital importance for the organism to regulate levels of these reactive species. A single mammalian enzyme, microsomal epoxide hydrolase (EPHX1, mEH), functions as a predominant pathway responsible for detoxification of xenobiotic epoxides, as well as bioactivation pathway for certain xenobiotic epoxides. In contrast, another important epoxide hydrolase, soluble epoxide hydrolase (EPHX2, sEH), has more recently been established as a mediator of epoxide hydrolysis of several endogenously derived epoxyeicosatrienoic acids (EETs), intermediates resulting from arachidonic acid metabolism. In this respect, EPHX2 is now characterized as an important regulator of physiological processes, such as blood pressure and inflammation, and has emerged as a promising therapeutic target for pharmacological intervention. This chapter reviews the biochemistry, biological regulation, genetics, and pharmacological relevance of these important enzyme systems.

13.2 INTRODUCTION TO EPOXIDE HYDROLASES

A wide variety of endogenously and exogenously derived lipophilic aromatic and aliphatic substances are metabolized initially through phase I biotransformation pathways, perhaps most notably by the cytochrome P450 monooxygenase enzymes (CYPs) [1]. The resulting oxidative metabolites include epoxide-containing intermediates that are subject to further metabolism by both phase I and phase II biotransformation pathways. Cells have developed the capacity to metabolize chemical epoxides through several pathways. Prominent among these are the epoxide hydrolases, including EPHX1 (EC 3.3.2.9) and EPHX2 (EC 3.3.2.10). The epoxide hydrolases belong to a subcategory of a broad group of hydrolytic enzymes that include esterases, proteases, dehalogenases, and lipases [2,3]. Epoxide hydrolases catalyze the hydrolysis of epoxides to their corresponding dihydrodiol (glycol) products. The hydration reactions often lead to changes in the biological functionality and/or the chemical reactivity of the resulting metabolite. Simple epoxides are hydrated to their corresponding vicinal dihydrodiols and arene oxides to *trans*-dihydrodiols. Although certain epoxides are relatively stable, for example, the pharmaceutical metabolite carbamazepine (CBZ) epoxide, other chemical epoxides are highly electrophilic and may react with cellular nucleophiles, such as DNA, RNA, and proteins [4]. With respect to xenobiotics, epoxide hydrolase metabolism results principally in detoxification. Importantly however, in certain instances, bioactivated toxic intermediates of xenobiotic substances may also be generated. Frequently, reactive and unstable epoxide metabolites, such as the bay-region and fjord-region diol epoxide intermediates arising from polyaromatic hydrocarbon (PAH) metabolism, have been identified as ultimate cytotoxic and carcinogenic reaction products [5,6]. The overall balance of xenobiotic metabolism between bioactivation and detoxification pathways catalyzed by EPHX1 determines the pharmacokinetic disposition and the ultimate fate of reactive intermediates within target cells. In contrast to EPHX1, the substrate specificity of EPHX2 is directed toward endogenously derived and generated epoxides, in particular, those resulting from the arachidonic acid metabolism cascade [3]. These intermediates function to regulate several important physiological processes, such as vascular reactivity and inflammatory responses.

13.2.1 Types and General Reactions of the Epoxide Hydrolases

Epoxide hydrolases are members of the α/β -hydrolase fold superfamily. The α/β -hydrolase fold domain structure α/β domain (ABD) is common to a number of hydrolytic enzymes of widely differing phylogenetic origins and catalytic functions. The α/β -hydrolase fold is characterized by a β -sheet core of five to eight strands linked by α -helices to form a $\alpha/\beta/\alpha$ sandwich structure [7]. The enzymatic activities contributed by members of this superfamily include esterase, lipase, and hydrolase functionalities [7,8]. Members of other gene families may also catalyze hydrolase activities, described briefly below.

Several types of mammalian epoxide-hydrolyzing enzymes have been characterized. These include (i) a microsomal enzyme specific for cholesterol 5,6-epoxide hydrolysis [9] that is little studied but distinct from the ABD-containing hydrolases otherwise discussed in this chapter; (ii) a membrane-associated hepoxilin A3 hydrolase, also likely distinct from the ABD domain structure, participates in arachidonic acid metabolism in the central nervous system and vascular cells [10]; (iii) a cytosolic leukotriene

A4 (LTA4) hydrolase that is quite distinct from the ABD protein family, as it possesses a zinc-binding domain and aminopeptidase activity, which mediates leukotriene metabolism and is consequently implicated in inflammatory and allergic responses [11,12]; (iv) an mEH (EPHX1) that is active in the metabolism of certain pharmaceuticals as well as a broad range of xenobiotic compounds, such as the mutagenic PAH-derived epoxides [2]; (v) an sEH (EPHX2) that is active in the metabolism of arachidonic-acid-derived epoxides and other endogenous epoxides [13]; and, the two more recently identified epoxide hydrolases, (vi) EPHX3 and (vii) EPHX4. EPHX3, also termed *ABHD9*, is a predicted α/β -hydrolase fold superfamily member that was identified in a genomics screen for DNA methylation markers associated with prostate cancer prognosis [14]. EPXH4 was identified by genomic-sequencing-based coding queries as a putative α/β -hydrolase-domain-containing protein, potentially associated, along with many other polymorphic markers, with altered response to hepatitis B vaccination [15]. Little other functional data are available describing EPHX3 or EPHX4, although apparent homologs of these hydrolases have been identified in *Caenorhabditis elegans*. EPHX3 and EPHX4 appear structurally much more closely related to EPHX2 than to EPXH1 and therefore may have a role in generating lipid-signaling intermediates [16].

The EPHX1 and EPHX2 members of the α/β -hydrolase fold family of proteins are two of the most well-investigated mammalian epoxide hydrolases. EPHX1 and EPHX2 are distinguished on their subcellular distributions, typically associated with microsomal and cytosolic distributions, respectively, but perhaps, more importantly, they possess highly distinctive substrate specificities and physiological roles. It is likely that two independent forces, namely, cytoprotection and cellular signaling, drove the evolution of EPHX1 and EPHX2, respectively [13]. Of the various epoxide hydrolases, that is, EPHX1, is *the only* hydrolase known to possess enzymatic activity toward xenobiotic-derived epoxides [13], and therefore, it is a principal focus in this chapter. However, EPHX2 is rapidly generating intense interest as a pharmaceutical target, with potential application in drug therapies aimed at treatment of inflammatory, cardiovascular, and other diseases. Consequently, this chapter reviews both these hydrolases and includes discussion of their respective functional, regulatory, and genetic features.

13.3 MICROSOMAL EPOXIDE HYDROLASE (EPHX1)

13.3.1 Introduction

As the earliest known epoxide hydrolase, EPHX1 plays a critical role in the metabolism of many xenobiotic compounds. The name of this epoxide hydrolase is derived from its primary cellular localization in the endoplasmic reticulum, that is, the microsomal environment. mEH appears unique among all the epoxide hydrolases for its exclusive role in the metabolism of xenobiotic-derived epoxides. EPHX1 is capable of hydrolyzing epoxides derived from xenobiotics of highly diverse structures, and the enzyme is especially capable of accepting substrates with bulky configurations, such as arene oxides [2,17]. The diol products of EPHX1 hydrolysis typically are less reactive chemical species relative to the parent compound, and the enzyme is therefore considered to generally foster detoxification. However, in the case of arene oxide metabolism, subsequent CYP-mediated ring oxidation of the hydrolyzed metabolite can lead to the

formation of vicinal diol epoxide species that may possess extremely high chemical reactivity [6,18].

The catalytic mechanism of EPHX1 involves two steps and is similar to that described for EPHX2 [19,20]. In this mechanism, first there is attack of a nucleophilic aspartic acid on the oxirane ring to yield an alkyl enzyme intermediate, and then subsequent hydrolysis of the intermediate by water. On the basis of sequence alignment analysis, the catalytic triad of EPHX1 was identified as consisting of Asp226, His431, and Glu404 [20,21]. Subsequently, site-directed mutagenesis experiments in a rodent model confirmed these catalytic amino acids as critical for EPHX1 enzymatic activity [3]. The human EPHX1 enzyme requires no cofactors for activity.

The human EPHX1 gene exists as a single copy and is located on chromosome 1, specifically at position 1q42.1 [22,23]. The coding region of the EPHX1 gene locus spans ~20 kb. The EPHX1 gene product exists as a monomeric protein of ~49 kDa and is composed of 455 amino acids [23]. Human EPHX1 is expressed in all tissues thus far examined, with highest levels in the liver, lower yet comparable levels in kidney and ovary, and lower levels in testis, lung, adrenal glands, and lymphocytes [13,24,25]. Developmentally, EPHX1 expression in human fetal tissues is relatively low during early gestation but increases as gestation progresses [26]. Research conducted with experimental rodent models indicates that the EPHX1 gene is responsive to chemical treatments [27–29]; however, evidence obtained from primary hepatocytes indicates that EPHX1 is only modestly transcriptional responsive in humans [30]. Early studies, cited above, drew attention to associations between EPHX1 and cancer. In humans, EPHX1 protein has been consistently identified in tumors from a variety of organs [31–35], fueling speculation that expression of this enzyme may play a molecular role in malignancy. Importantly, experiments employing null mice have demonstrated that EPHX1 expression is a critical determinant in PAH-induced carcinogenesis [36].

13.3.2 Biological Function of EPHX1

Over the last few decades, EPHX1 has been recognized primarily for its role in xenobiotic metabolism. However, several intriguing observations also suggest that EPHX1 may play a role in modulating physiological functions. For example, several lines of evidence indicate that EPHX1 may play a role in steroid synthesis and/or metabolism [13]. For example, estroxiol and androstene oxide are good EPHX1 substrates [37,38]. Consistent with this theme, an early study identified EPHX1 as a subunit of the anti-estrogen binding site [39]. Furthermore, EPHX1 is relatively highly expressed in ovaries [40,41], especially in follicle cells [42]. One hypothesis is that EPHX1 may be important for cellular protection against reactive metabolites of endogenous compounds, such as epoxy steroids. Human EPHX1 is expressed and developmentally regulated in fetal tissues [26], suggesting that it may be important for protection from toxic epoxide intermediates during embryonic and fetal development. In this light, a recent report indicated that oviductal EPHX1 expression is upregulated during the process of mouse embryogenesis and that increased oviductal EPHX1 may help reduce levels of reactive oxygen species [43]. These functions may represent protective effects of EPHX1, potentially enhancing mouse embryo developmental processes.

In addition to a potential role in steroid homeostasis, another study suggested that EPHX1 is a functional component of the vitamin K₁–oxide reductase complex in rat liver microsomes [44]. Also, a role for EPHX1 in bile acid homeostasis has been

suggested, as EPHX1 was identified by one group of investigators as part of a multiprotein transport system that is responsible for sodium-dependent bile acid uptake in liver [45–48]. To further this view, several reports have indicated that EPHX1 is expressed at the hepatocyte plasma membrane and in the endoplasmic reticulum where it can exist in two topological orientations and that bile acid uptake appears dependent on EPHX1 expression at the plasma membrane [48]. However, the specific role and relative importance of EPHX1 in the physiologic function of bile acid transport is controversial, in that another study was unable to reproduce these purported activities of EPHX1 [49]. Possibly, development and use of potent and selective EPHX1 inhibitors may help to address the still open questions as to a potential role of EPHX1 in bile acid transport and/or vitamin K reductase participation.

As EPHX1 is expressed ubiquitously in many species, including mammalian, plant, and single cell organisms [50], and several intriguing lines of evidence for its endogenous functionality have been advanced, it seems logical to postulate an important physiological role for its activity. However, it should be noted that an EPHX1 null mouse model has been established [36]. These null mice appear healthy and reproduce with normal efficiencies. Thus, lack of EPHX1 expression in the mouse does not appear to be physiologically detrimental, presenting somewhat of a puzzling dilemma regarding the potential endogenous role of the enzyme in mammalian systems.

13.3.3 Substrates and Inhibitors

EPHX1 exhibits a large range of substrate specificity, and most epoxide intermediates are generated *in situ* by phase I oxidation reactions [51]. The substrates of EPHX1 broadly range from aliphatic epoxides to polyaromatic oxides. The subsections below review a number of chemically derived, environmentally relevant, and pharmaceutical substrates for the enzyme, together with the biological implications of these reactions.

13.3.3.1 Environmental/Xenobiotic. EPHX1 has been recognized as an important contributor to the metabolism of xenobiotic epoxides, including numerous environmental contaminants. Historically, several different substrate probes for EPHX1 have been employed for routine assessments of enzymatic activity in biochemical reactions. These include benzo[*a*]pyrene (B[*a*]P)-4,5-oxide [52,53], *cis*-stilbene oxide [54], styrene oxide [55], CBZ-10,11-epoxide [56,57], and naphthalene-1,2-oxide [57,58]. Fluorescent substrates for EPHX1 have more recently been developed. The highest activity for both rat and human EPHX1 was obtained with the fluorescent substrate cyano(6-methoxy-naphthalen-2-yl)methyl glycidyl carbonate [59]; however, this compound cannot be used with crude enzymatic preparations due to interfering reactions.

Common environmental toxins that generate epoxide intermediates metabolized by EPHX1 include 1,3-butadiene [60,61], styrene [62], and benzene [63]. Illustrations of the structural features of these substrates and associated reactions are shown in Fig. 13.1. In addition, several other xenobiotic compounds are metabolized to epoxide intermediates, such as aflatoxin B₁ [64], the nitropyrenes [65,66], and the PAHs, including chrysene, naphthalene, anthracene, and B[*a*]P [67,68].

As a case in point, PAHs are products of incomplete combustion of organic matter and are widespread environmental contaminants found in automobile exhaust, cigarette smoke, air, water, food, and soil. PAHs are considered procarcinogens because they

Figure 13.1 Common xenobiotic substrates of EPHX1 and their general reaction schemes. Step one is commonly mediated via cytochrome P450, while step 2 is mediated via EPHX1.

require metabolic activation to electrophilic reactive metabolites to exert their mutagenic and tumorigenic activities. Three principal pathways of metabolic activation have been proposed for the activation of the PAHs. These involve (i) the formation of diol epoxides by several CYPs, where CYP1A1, CYP1B1, and others can play a major role [69]; (ii) the formation of radical cations catalyzed by peroxidases [70]; and (iii) the formation of reactive intermediates catalyzed by dehydrogenases and other reductases [71,72]. However, the biological effects of a number of PAHs, including their mutagenicity and carcinogenicity, are largely dependent on enzymatic activation to dihydrodiol epoxide intermediates [73], which are formed by a three-step process: initial epoxidation by the CYPs, subsequent EPHX1-mediated hydrolysis to the *trans*-dihydrodiol, followed by a second epoxidation at the adjacent double bond [74]. The critical nature of EPHX1 bioactivation in PAH-induced carcinogenesis is further demonstrated in EPHX1 null mice, which are completely resistant to the tumorigenic effects of the PAH dimethylbenz[*a*]anthracene in a complete carcinogenesis assay [36].

The mutagenic and carcinogenic potency of the PAHs appears largely dependent on their structural features. As indicated previously, K-region PAH oxides, such as the B[*a*]P-4,5-oxide, are often used as model substrates for EPHX1 activity. Although mutagenic, these derivatives are not the principal determinants of PAH-induced carcinogenesis. Rather, it is the terminal ring PAH oxides, away from the respective bay or fjord region and when hydrolyzed by epoxide hydrolase, that lead to production of the proximate PAH carcinogen, the *trans*-dihydrodiol, which in turn is metabolized to the ultimate carcinogen, the diol epoxide. The strong steric interactions of the fjord-region

Figure 13.2 Examples of polycyclic aromatic hydrocarbons illustrating both bay- and fjord-region centers that are subject to epoxidation reactions by cytochrome P450s and subsequent hydrolysis by EPHX1.

force the molecule to distort from planarity. EPHX1 contributes both to the formation of highly reactive and mutagenic bay-region (planar PAHs) and fjord-region (nonplanar PAHs) diol epoxide intermediates [6,75,76], with the corresponding mutagenic and tumorigenic potencies of these substances largely dependent on their structural features. In particular, diol epoxides derived from PAHs that possess a fjord region exhibit substantially more potent carcinogenic activities than those derived from bay-region PAHs [6]. Examples of both bay-region and fjord-region PAHs are shown in Fig. 13.2. The diol epoxides thus generated react readily with mutational hot spots in DNA to form stable adducts both *in vitro* and *in vivo* [77,78]. If these adducts are not repaired, they result in misreplication and mutagenesis [77,78]. The fjord-region, nonplanar diol epoxides, such as dibenzo[a,h]pyrene, react more favorably with deoxyadenosine (dA) than deoxyguanosine (dG) in DNA and fjord-region-modified DNA adducts are more difficult to repair than a bay-region adduct [79–82]. Given this backdrop, it is of interest that several epidemiologic investigations have now implicated human EPHX1 gene-coding-region polymorphisms as a risk modifier for lung cancer incidence [83].

13.3.3.2 Pharmacological. Although many pharmaceuticals undergo oxidative metabolism, principally in the liver but also in other organs, and the CYPs play prominent roles in these initial enzymatic reactions, it is perhaps surprising that not many known pharmaceutical agents undergo sequential enzymatic processing by EPHX1. In part, this is likely due to the extensive preclinical testing that developmental drug candidates are subjected to, and it is logical to assume that compounds exhibiting an avid potential to be metabolized into reactive epoxides are typically eliminated from further development in early toxicity screens. However,

Figure 13.3 Examples of anticonvulsant medications and other pharmacological agents that are implicated in EPHX1 metabolism schemes. Arrows represent epoxidation reaction sites.

EPHX1 has been implicated in the metabolism of several categories of drugs, including commonly used anticonvulsant, psychostimulant, and anticancer drugs.

Historically, aromatic anticonvulsant drugs, such as phenobarbital (PB), diphenylhydantoin (phenytoin), and CBZ, have been widely employed in the treatment of seizure disorders and are the most readily recognized as having interactions with epoxide hydrolase [84]. Figure 13.3 illustrates chemical structures of selected anticonvulsant agents that are metabolized either to epoxide intermediates, which are in turn substrates for EPHX1, or pharmacological structures, which are otherwise known to affect the metabolism of the epoxide hydrolase pathway. Biotransformation pathways for these drugs typically involve initial phase I metabolism by various CYPs that can then result in the generation of arene oxides, which are substrates for EPHX1. Idiosyncratic

adverse drug reactions (ADRs) can occur following treatment with certain anticonvulsants, and in several early studies, polymorphism in EPHX1 expression was implicated as a risk factor for this response [85,86].

For example, phenytoin is an older anticonvulsant medication that has a widespread usage. It is likely metabolized, in part, through an arene oxide intermediate [87]. Toxicity concerns surrounding its use have been frequently raised, and certain evidence implicates EPHX1 in this respect. For example, a case study published in 1988 suggested the protective role for EPHX1 in anticonvulsant hypersensitive syndrome, indicating that patients susceptible to anticonvulsant toxicity had decreased epoxide metabolism activity [88]. In one instance of ADRs, strikingly reduced levels of mEH RNA were demonstrated in an affected patient [89]. The teratogenic risk of fetal hydantoin syndrome, related to exposure to phenytoin, was also reported as increased in a study in subjects with low EPHX1 enzymatic activity [90]. However, subsequent studies that specifically examined the association of EPHX1 amino acid polymorphisms with susceptibility to ADRs found no apparent association [91,92]. It should be noted that the population sizes evaluated in these latter studies were small and additional EPHX1 polymorphisms, for example, those residing in the respective promoter regions of the gene have now been identified [93,94] but have not yet been assessed as potential risk contributors in these respects.

Given the long-standing use of PB for the effective treatment of convulsant disorders, concerns with its use have also arisen. The metabolism of this agent is also projected to proceed, in part, through an arene oxide intermediate [95]. Although PB is a liver-tumor-promoting agent in rodents, epidemiological studies in PB-exposed populations have not uncovered enhanced risk to liver cancer in humans, even following its long-term use [96,97]. Therefore, the larger concern with the use of PB is likely due to its induction effects on various biotransformation pathways [98] that may in turn lead to ADRs or drug–drug interactions. However, the question of whether PB may induce epoxide hydrolase activities in humans is open. In studies conducted using primary hepatocyte cultures from human donors, this agent appears to only modestly effect EPHX1 levels [30], but in general, the issue of interindividual variability in response to chemical inducers certainly adds complexity to these issues [99].

CBZ is another older-generation therapeutic for the treatment of epileptic disorders and has historically been one of the most widely prescribed frontline medications for this syndrome [100]. The principal bioactive metabolite of this compound is the CBZ-10,11-epoxide derivative, an epoxide that is relatively stable and readily detected in serum [100,101]. CBZ-10,11-epoxide is a substrate for EPHX1. Using genetic haplotype-mapping approaches, Japanese investigators reported apparent correlation with EPHX1 coding region genotype status and intrinsic clearance measures of CBZ-10,11-epoxide [101]. More recently, results of independent studies also suggested that the genetic status of EPHX1 may be a useful predictor of CBZ maintenance doses in prescribed populations [102]. Furthermore, it has been reported that valproic acid, another anticonvulsant medication, potentially inhibits EPHX1 activity, thereby altering steady-state levels of CBZ-11,12-oxide in cotreated patients [103]. However, results of other investigations indicate that the glutathione transferase system is likely involved as well in determining the disposition of CBZ-11,12-oxide serum levels [104].

Methamphetamine hydrochloride (METH) is a highly addictive and popular illicit drug that is neurotoxic and presents an addiction that is very difficult to treat. The biotransformation of METH has been investigated. On smoking, pyrolysis products are

derived that include *trans*-phenylpropylene, a product that is likely to undergo oxidation metabolism by the CYPs, leading to a potentially reactive and neurotoxic epoxide intermediate [105]. Interestingly, experimental evidence indicates that this neurotoxic epoxide intermediate is indeed a substrate of EPHX1 [105]. Using an EPHX1 knockout mouse model, a recent report identified that EPHX1 expression plays an important role in detoxifying the reactive epoxide intermediates of METH and in attenuating METH drug addiction [106]. This finding offers a novel therapeutic approach for potential prevention or attenuation of the long-term consequences of METH use disorders in humans.

17-(Allylamino)-17-demethoxygeldanamycin (17AAG) is a potent antiproliferative drug that has been in clinical trials for treatment of chronic lymphocytic leukemia as well as kidney tumors, especially in young patients [107]. Its mechanism of action is through targeting of Hsp90-associated activities and disruption of protein-tethering interactions. 17AAG is extensively metabolized; a diol metabolite is among the major products detected. EPHX1 is likely involved in the production of the diol metabolite, subsequent to hydrolysis of an epoxide intermediate formed on the allyl side chain of 17AAG [108]

13.3.3.3 Inhibitors. In early studies, several epoxide-containing compounds were discovered as EPHX1 inhibitors. For example, 1,1,1-trichloropropene-2,3-oxide [109,110] and cyclohexene oxide [111,112] have been widely used as EPHX1 inhibitors. In addition, other investigators have described primary ureas, amides, and amines [113,114], as well as heavy metals such as divalent mercury and zinc [115], as EPHX1 inhibitors. More recently, Hammock and colleagues screened a series of amides and identified 2-nonylsulfanyl-propionamide as a competitive inhibitor of EPHX1 enzymatic activity, exhibiting a K_i of 72 nM, thus establishing this agent as the most potent inhibitor identified to date. These agents represent useful *in vitro* tools for assessing the involvement of EPHX1 activity in the characterization of chemical and pharmaceutical biotransformations.

13.3.4 Genetic Polymorphisms

Human pharmaceutical and xenobiotic metabolisms are subject to large interindividual differences [116,117]. A variety of parameters are known to contribute to this phenomenon, and genetic constitution is likely of major importance [118]. In addition to the inherited differences in chemical metabolism's capacity and specificity, additional contributors to interindividual differences in risk of toxicity resulting from xenobiotic exposure include age, gender, disease states, tissue differences, and environmental influences, such as diet, smoking habits, occupational exposure to chemicals, and concurrent exposure to other drugs [117,119]. Despite the present era of genomics, achieving a detailed comprehension of the interplay of such variables with man's inherent genetics remains a formidable challenge for the foreseeable future. The ability to predict potential hazards resulting from human exposure to pharmaceuticals as well as other foreign chemicals requires that we elucidate the genetic and regulatory factors that contribute importantly to the risk scenarios underlying human variability in biotransformation and xenobiotic disposition.

Large interindividual variations in EPHX1 activities have been described in human tissues. For example, EPHX1 activity was reported to vary from 8-fold to up to 63-fold

in panels of human liver samples [53,120,121]. After the full-length human EPHX1 DNA sequence was cloned and compared, two nonsynonymous amino acid changes were identified in the EPHX1 coding region. The polymorphism in exon 3 corresponds to amino acid position 113 and results in Tyr (Y) to His (H) substitution (rs1051740). An exon 4 polymorphism at position 139 (rs2234922) encodes a His (H) to Arg (R) substitution. For the polymorphism at position 113, 7.6% individuals were observed with homozygous His, and the frequency of 139 A/A is 4.6%. The distribution of the two alleles follows Hardy–Weinberg equilibrium [2,122]. There are other nonsynonymous polymorphisms reported or listed in the NCBI dbSNP database, but to the authors' knowledge, these polymorphisms either have not been validated or have only been identified at a very low allelic frequency. Consequently, the 113Y/H and 139H/R polymorphisms are recognized currently as the most common EPHX1 amino acid variants in the human population. As many commonly encountered environmental chemicals undergo epoxide metabolism, there is an interest in assessing genetic variation in EPHX1 as a potential risk modulator for other chemicals.

Since the initial identification of these two primary EPHX1 coding polymorphisms, a surprisingly large number of epidemiologic investigations have examined the potential association of disease incidence with EPHX1 genotype. An early review of selected molecular epidemiological investigations examining associations of EPHX1 genotype with cancer susceptibility has been published [123]. Perhaps, the most consistent associations implicate EPHX1 coding region polymorphisms as a risk factor for lung cancer [124–130]. In 2002, Lee *et al.* [128] conducted a meta-analysis of seven previously published studies and reported a significant decrease in lung cancer risk (OR = 0.70, 95% CI = 0.51–0.96) associated with the “low activity” exon 3 H113 homozygous EPHX1 genotype, after adjustment for age, sex, smoking, and center. In 2006, a human genome epidemiology (HuGE) review and meta-analysis of 13 case-control studies was published [83], similarly concluding that the low activity variant H113 genotype of EPHX1 was associated with decreased risk of lung cancer (OR = 0.65; 95% CI = 0.44–0.96). In contrast, other reports have indicated an increased risk of chronic obstructive pulmonary disease (COPD) [131,132] and emphysema [132] with the H113 genotype, despite both diseases being linked to smoking behaviors. Another report has indicated a protective association of the Y113H genotype with COPD [133]. The paradoxical results may perhaps be explained if the various EPHX1 allelic proteins exhibited differential activities on specific substrates involved in diverse disease etiologies. Disease associations with EPHX1 polymorphism at the exon 4/Y139R position have also been reported [134–136]. The mechanistic basis for these associations in relation to the enzymatic function of the xenobiotic hydrolase remains unknown.

Genetic differences in EPHX1 also have been reported as a potential risk modulator of toxicity caused by styrene [137] and butadiene [138,139] exposure in human worker populations, although other studies have not confirmed such associations [120,140]. Interestingly, bioactivation of aflatoxin B₁ by cytochrome P450 enzymes generates a highly reactive epoxide metabolite, and incubation with the EPHX1 enzyme is reported to reduce the aflatoxin's carcinogenic effect [64]. In these respects, an initial study indicated a risk association with hepatocellular carcinoma and EPHX1 genotype [141]; however, subsequent analyses were also not able to confirm this association [142].

It should be noted that many of the published EPHX1 molecular epidemiologic reports frequently refer to quantitative functional descriptors for the respective EPHX1

genotypes, indicating, for example, “the low activity allele” or “the high activity genotype.” However, the relative enzymatic contribution of the commonly studied EPHX1 Y113H and H139R polymorphisms has been examined functionally to only a limited extent, and only modest support for any enzymatic/catalytic difference among the EPHX1 variants exists. For example, using the K-region, B[a]P-4,5-epoxide as substrate, the four potential allelic variants of EPHX1 were evaluated for relative functional activities using sources of EPHX1 protein variously derived from transfected COS-1 cells, baculovirus-infected Sf9 cells, and genotyped samples of human liver microsomes [122,143]. Following normalization to immunoreactive levels of EPHX1 protein, only minimal differences in enzymatic specific activities were apparent among the variant isoforms. Similar results were reported using *cis*-stilbene oxide, another model substrate for EPHX1 [143]. Other investigators also examined the enzymatic capacity of the respective EPHX1 variants and failed to discern a correlation between EPHX1 polymorphism and enzymatic activity [57]. Therefore, despite the many epidemiologic studies that have used descriptors such as “low activity allele” or “high activity allele” in an attempt to explain the functional basis of their results, the underlying basis for the EPHX1 activity claim is not yet well substantiated. Given the important role of EPHX1 in the biotransformation of reactive xenobiotic epoxides and the apparent wealth of epidemiological association of genetically encoded differences in EPHX1 protein structure with the incidence of various diseases, the exact functional impact of EPHX1 polymorphism requires more rigorous study. Moreover, the interaction of EPHX1 with other metabolizing enzymes, such as the glutathione *S*-transferases and *N*-acetyltransferases, may additionally contribute to modulate the association with lung cancer [144]. Since the EPHX1 and EPHX2 metabolic pathways are each intimately connected to cytochrome P450-mediated catalysis, it is very likely that a web of polymorphisms among these proteins will prove to be important pharmacogenetic considerations with respect to medical diagnosis and therapy.

Some studies of the EPHX1 protein variants suggested that these coding region polymorphisms may affect protein stability. For example, in a panel of 40 human livers, EPHX1 enzyme activities demonstrated strong correlation with the respective protein levels [53]. However, neither the EPHX1 protein nor its activity was associated with the EPHX1 mRNA levels, which suggested some posttranscriptional-mechanism-regulated EPHX1 protein expression. The translational efficiency, mRNA half-life, and protein half-life of mEH allelic variants have been assessed by *in vitro* transcription and translation using constructs encoding four EPHX1 alleles. The coding region polymorphisms do not appear to affect translational efficiency or mRNA decay rate. Although the calculated EPHX1 variant protein half-lives suggested that polymorphic amino acid substitution may result in altered protein stability [145], these differences in protein half-lives were small, and it is unclear whether they affect overall functional protein levels.

As previously discussed, EPHX1 is largely responsible for the formation of PAH reactive metabolites, and fjord-region diol epoxides exhibit substantially more potent carcinogenic activities than those derived from bay regions, and fjord-region-modified DNA adducts are more difficult to repair than the bay-region adducts [79–82]. The role of the EPHX1 polymorphic variants in the formation of these carcinogenic PAH metabolites has not been assessed. It is interesting to speculate that the EPHX1 protein variants may exhibit differential catalytic activities toward these substrates, which in turn could render some individuals more susceptible to PAH-induced cancers. Similarly,

as also presented earlier, EPHX1 genotype has been implicated as a determinant of steady-state serum levels of certain anticonvulsant medications, as well as incidence of ADRs, following administration of select anticonvulsant agents. These potential functional relationships will require additional detailed study in *in vitro* assays and in clinical populations in order to ascertain.

In addition to the polymorphisms encoding amino acid change, DNA sequence variation has been identified in the 5'-flanking of human mEH, proximal to the coding region of the gene [93]. Heterologous expression of DNA fragments containing the polymorphisms indicated variable levels of reporter gene activity, suggesting that variation in this portion of the human EPHX1 gene may also contribute to functional expression levels. When considering the association of genetic polymorphisms with the risk of human disease, structural region EPHX1 polymorphisms alone likely do not account for the complete spectrum of variation influencing EPHX1 activity; polymorphisms occurring within the 5'-regulatory regions of the gene may represent additional and, perhaps, important considerations.

13.3.5 Regulation of Expression

Alterations in the EPHX1 protein level and/or activity will likely affect an individual's xenobiotic metabolism capacity. Therefore, both the genetics and regulation of EPHX1 expression in human tissues may represent an important determinant of interindividual differences in chemical responsiveness, resulting toxicities, and, perhaps, carcinogenic outcomes resulting from select chemical exposures.

13.3.5.1 Transcriptional Regulation. In rodents, EPHX1 expression can be highly inducible by a variety of compounds, including PB, 3-methylcholanthrene, polychlorinated biphenyls, *trans*-stilbene oxide [146], certain peroxisome proliferators [13], radiation [147], heavy metals [2], and select steroids [38]. In contrast, studies of human EPHX1 induction capacity have not yielded comparable results. For example, analyses of the EPHX1 transcript levels *ex vivo* in primary cultures of human hepatocytes obtained from seven individual donors subjected to *in vitro* exposures to five prototypic inducing agents, specifically, PB, dexamethasone, Aroclor 1254, ciprofibrate, β -naphthoflavone, and *bis*-hydroxyanisole, revealed that expression levels were only modestly affected by these agents in primary human hepatocytes [30]. Therefore, in this regard, the EPHX1 induction results that have been obtained in rodents cannot be easily extrapolated to humans.

13.3.5.2 Regulation by Alternative Promoters. It is well established that RNA diversity in mammals is expanded markedly through the use of alternative promoters and differential RNA splicing mechanisms, and it has been shown that these mechanisms play a role in modulating the EPHX1 gene. Initially, Gaedigk *et al.* reported complex splicing processes at the exon 1/2 boundary, which apparently generated eight putative alternative exon 1 variant sequences in addition to the well-known exon 1, E1, previously defined from liver [148]. However, it was later determined that many of the previously characterized alternative exon 1 sequences were misidentified and rather shared identity with sequences derived from the signal recognition particle 9-kDa structural gene (SRP9, NM003133), a gene that exists upstream of the EPHX1 coding region [24]. The latter study utilized a more stringent 5'-rapid amplification of cDNA

ends (RACE) technique to identify two bona fide unique first exons from human-liver-derived mRNA samples, termed *E1* and *exon 1b* (*E1-b*). The *E1* transcript initiated from the initially characterized promoter and was positioned immediately proximal to the exon 2 of *EPHX1* coding region, while the *E1-b* variant exon 1 was localized to a genomic region ~18.5 kb upstream of exon 2. Northern blot RNA hybridizations demonstrated that the *E1-b* variant was expressed ubiquitously throughout panels of both human fetal and adult tissues. In contrast, the *E1* transcript was expressed almost exclusively in liver [24]. A more recent study confirmed and extended these observations and further substantiated that the far upstream *E1-b* promoter functions as the primary driver of *EPHX1* expression in human tissues, including liver [25]. Furthermore, genome browser sequence comparisons of the *EPHX1* *E1-b* promoter conducted among 28 vertebrate species revealed that the *E1-b* promoter region was highly conserved only among primate species [94], suggesting that the regulation of *EPHX1* expression in species such as mouse and rat may involve distinct promoter regulatory mechanisms. Currently, the nuclear factor interactions and associated molecular mechanisms regulating this critically important transcriptional domain of *EPHX1* are under intensive investigation.

With respect to the proximal and initially characterized *E1* promoter, the basis for its liver-specific functionality was examined by several investigators. A number of cis-regulatory elements were identified that appear to contribute toward its hepatic transcription character, including GATA and HNF3 motifs [24]. For example, mutation of the GATA site at position -110/-105 resulted in a marked (70%) decrease in basal transcription activities driven by the *E1* promoter in human hepatoma cells, and GATA-4 was identified as the principal GATA family member interacting with the respective motif. Interestingly, both HNF3 α and HNF3 β were found to interact with the HNF3 element at position -96/-88, but they acted to negatively regulate GATA-4 function in hepatic cells. GATA-4 has been described previously as a regulator of *EPHX1* tissue-specific expression, with assistance from other tissue-restricted transcription factors including the CCAAT/enhancer-binding protein α (C/EBP α) and nuclear factor Y (NF-Y). These factors appear to form a complex and bind directly to the CCAAT box within the *E1* promoter, activating hepatic *EPHX1* *E1* transcription [149].

13.3.5.3 Transposable Elements. Characterization of the entire human *EPHX1* gene locus has uncovered a number of remarkable features. The use of an alternative gene promoter, located ~18 kb upstream from the coding region of the gene, was described above, and it is the predominant driver of *EPHX1* expression in human tissues. Another feature of the *EPHX1* gene locus relates to the presence of repetitive DNA elements. Mammalian genomes are complex and dynamic, merely a small fraction is occupied by protein coding exons, while up to 50% is contributed by repetitive elements, with the remaining 48% comprising “unique DNA” [150]. Nearly half of the human genomic sequences are derived from ancient transposable elements (TEs), which encompass both transposons and retrotransposons, including short interspersed element (SINE) and long interspersed element (LINE), long terminal repeats (LTRs), and DNA transposons [151]. TEs are DNA sequences that are capable of integrating from one site in the genome to a new one via a “cut and paste” mechanism [152]. First described as “junk” DNA, the importance and function of TEs have been increasingly appreciated recently. These TEs or mobile elements participate in genome formation and benefit the evolution of genes by affecting their functions. TEs have the ability to promote

genetic diversification and regulatory variation by serving as recombination hot spots, altering protein coding content or by regulating gene transcription [153,154]. TEs have been shown to serve as alternative promoters for many genes, including aromatase P450 (CYP19; [155]), carbonic anhydrase 1 [156], and bile acid CoA: amino acid N-transferase [157], resulting in tissue-specific regulation of gene expression.

Alu elements are a particularly important type of TE and comprise the major components of SINEs that exist in the human genome; their 1.1 million copies occupy over 10% of the human genome and contribute to a significant portion of human genetic diseases [158]. It is therefore of interest and potentially of functional importance that the far upstream E1-b promoter region of human EPXH1 is replete with repetitive elements, including those of the Alu class, and that humans are genetically polymorphic for the inclusion of a specific double Alu repeat cluster [94,159]. Presence of the double repeat element appears to reduce transcriptional activity of the E1-b promoter in cell lines of different tissue lineage [94]. If these results also apply to the *in vivo* situation, differences in EPXH1 expression and corresponding capacities to conduct xenobiotic metabolism, may arise from these or other promoter region polymorphisms and may have an important bearing on interindividual risk factors associated with epoxide catalysis in target cells.

13.3.6 Summary/Pharmacological Implications

In summary, EPXH1 is an important xenobiotic enzyme, contributing critical activities toward both detoxication and bioactivation processes. The identification of human genetic polymorphisms within the EPXH1 gene locus may represent risk variables to various disease syndromes that include cancers [83], certain pulmonary diseases [132,160], preeclampsia [161], METH addiction [106], and adverse reactions to pharmacotherapies. For example, in the case of adverse drug reactions, anticonvulsant hypersensitivity syndrome has been postulated to potentially involve EPXH1 [88,89]. The transcriptional regulation of human EPXH1 appears to differ markedly from that in rodents, for example, involving the primary contribution of a far upstream gene promoter region [24,94]. Elucidating the molecular mechanisms of EPXH1 transcriptional control in human tissues and the potential genetic contribution of EPXH1 to the etiology of human disease remain important venues for future research.

13.4 SOLUBLE EPOXIDE HYDROLASE (EPHX2)

13.4.1 Introduction

Although its existence was controversial in early studies, sEH (EPHX2) was first identified as a separate enzymatic activity several years after the discovery and characterization of EPXH1. Initially, the respective enzymes were largely distinguished by their soluble fraction versus microsomal subcellular localization [55,162]. Both enzymes were originally thought to participate in xenobiotic metabolism, although EPHX2 was recognized at its inception for its role in the metabolism of a terpenoid juvenile hormone mimic in insects [55,162]. Relatively early, EPHX2 was recognized for its preference for *trans*- over *cis*-substituted epoxides of sterically hindered substrates, and hence, *trans*-stilbene oxide has often used to distinguish EPHX2 activity

from EPHX1 activity, as the latter enzyme exhibits strong preference for *cis*-stilbene oxide [54]. However, more recent experimental evidence has firmly established that the major role of EPHX2 is in the metabolism of endogenous epoxy fatty acids, with the EETs emerging as the best studied EPHX2 substrates [13]. Although the endogenous role of EPHX2's metabolism seemingly shifts its focus away from its function as a drug-metabolizing enzyme, the theme of this text, the enzyme has taken on new and important identities that position it squarely as an important target for pharmacological intervention. Therefore, these latter therapeutic dimensions of EPHX2 are the primary focus of the subsequent sections.

Human EPHX2 is localized on chromosome 8 at position 8p21-p12 [163], a locus comprising a single gene that consists of 19 exons, and encodes a 62.5-kDa protein (EC 3.3.2.3) [164]. Unlike the monomeric EPHX1 protein, the EPHX2 protein exists largely as homodimers of its monomeric subunit [165–168]. Each EPHX2 protein monomer is composed of two functional domains joined by a proline-rich linker. The C-terminal domain contains the α/β -hydrolase structure homologous to haloalkane dehalogenase and is responsible for the epoxide hydrolase activity [13,169]. The N-terminal domain is similar to haloacid dehalogenase, and functions as a lipid phosphatase [13,170,171]. EPHX2 is widely distributed in numerous tissues, with highest activity in the liver [172], followed by the kidney [173], where its distribution is concentrated within the renal cortex. The primary isolation of EPHX2 is from the cytosolic or soluble fraction, but in some cases, EPHX2 activity was reportedly localized in peroxisomes [174]. In rodents, drugs such as the peroxisome proliferator-activated receptor α (PPAR α) agonists are strong inducers of EPHX2 [175,176], although functional PPAR α response elements have not been identified in the upstream of human EPHX2 gene.

13.4.2 Biological Functions

Numerous investigations have now demonstrated the importance of EPHX2 in the regulation of high blood pressure [177,178] and inflammation [179,180]. Recently, with the development of EPHX2 inhibitors, the generation of EPHX2 null mice and the analysis of EPHX2 genetic polymorphisms, a more detailed understanding of the important biological role of mammalian EPHX2 has emerged.

As indicated earlier, it has become increasingly clear that fatty acid epoxides are the major endogenous substrates for EPHX2, with the cytochrome P450-derived epoxides of arachidonate acids (EETs) being the most well studied [13]. An overview of arachidonic metabolism is presented in Fig. 13.4. Numerous investigations have now demonstrated that EETs are chemical mediators that play significant roles in cardiovascular and renal regulation, modulating physiological parameters including hypertension, inflammation, angiogenesis, and mitogenic effects in the kidney [181]. Over the past several years, selective pharmacological EPHX2 inhibitors, such as 12-(3-adamantan-1-yl-ureido)-dodecanoic acid, have been designed with the potential to treat a variety of disease situations [3,114].

Several biologically imported EETs are diagramed in Fig. 13.5. Generally, the hydrolysis catalyzed by EPHX2 eliminates the biological activity of the lipids. EPHX2 was therefore postulated to play a role in blood pressure regulation, as 14,15-EET is a potent vasodilator. In subsequent studies, EPHX2 null mice were found to exhibit decreased blood pressure [177]. Moreover, recent physiological and genetic studies in a hypertensive rat model have further delineated the important role of EPHX2 in

Figure 13.4 Overview of the arachidonic acid metabolism cascade. PG, prostaglandin; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid.

Figure 13.5 Illustration of several epoxyeicosotrienoic acid intermediates that display reactivity with EPX2.

blood pressure regulation and as a susceptibility factor for heart failure [182,183]. Therefore, inhibition of EPX2 is considered a new therapeutic approach for hypertension. In addition to vasodilatation, EETs also display anti-inflammatory role in vascular endothelial cells by inhibiting cytokine-induced NF- κ B transcription. It has been suggested that EPX2 may play a key role in the regulation of inflammation by metabolizing anti-inflammatory EETs and in bioactivation of the toxic and proinflammatory effects of leukotoxin. In cell culture, inhibiting EPX2 results in EET accumulation and enhances their anti-inflammation effect [3]. Also in these respects, investigations conducted in null mouse models have demonstrated that EPX2 deletion attenuates renal injury and inflammation in a high salt model [184].

Similarly, on the basis of studies conducted in cardiovascular models of ischemic injury and hypertrophy, EPX2 has emerged as a potentially important pharmacological target in cardioprotection. Indications are that inhibitors of enzyme may offer therapeutic potential for a broad range of cardiovascular diseases [185]. As endothelial dysfunction contributes to the development of coronary heart disease, contribution

of EPHX2 in the metabolism of the EETs in vasculature tissues is likely an important factor in the regulation of endothelial function [186]. Interestingly, EPHX2 was recently identified as a heart failure susceptibility gene. These studies reported that the metabolism of cardioprotective EETs are affected by EPHX2 allelic variants that result in altered transcript and protein levels [183].

13.4.3 Genetic Polymorphism

Approximately 755 single nucleotide polymorphisms (SNPs) for human EPHX2 are cataloged currently in the NCBI SNP database. However, the great majority of these SNPs reside in noncoding regions of the gene or code for synonymous nucleotide substitutions. Initial analyses of EPHX2 genetic polymorphism in humans revealed the existence of two nonsynonymous polymorphisms, resulting in altered human sEH/EPHX2 amino acid sequences with associated alteration in enzymatic function or stability [187]. One involved a polymorphism at residue 287 (Arg287Gln; rs751141), where the more common arginine is nonconservatively substituted with glutamine [187,188]. A second coding region variant (rs71868122) involved an unusual trinucleotide insertion encoding an additional arginine residue, following the normal serine in position 402 [187]. Additional nonsynonymous polymorphisms have since been identified, including a Lys55Arg (rs4150795) amino acid substitution. All these structural EPHX2 polymorphisms appear to affect enzymatic function. Results of *in vitro* enzymatic assays as well as comparative molecular modeling analysis based on the crystal structure of EPHX2 indicate that the Arg287Gln variant possesses decreased activity as well as decreased protein stability relative to the reference protein [187,189]. On the other hand, the Lys55Arg variant appears to encode a more highly active form of EPHX2 [186,189].

Results of molecular epidemiological studies in human populations assessing the potential association of EPHX2 genetic polymorphism in human disease have yielded interesting findings. For example, in a study of risk factors associated with familial hypercholesterolemia, plasma cholesterol levels were elevated in individuals carrying both the Arg287 allele and a mutation in the low density lipoprotein receptor (LDLR) [190]. Interactive effects of Arg287 with carriers of the LDLR polymorphism were also noted between increased risk of cardiovascular disease and incidence of familial hypercholesterolemia [190]. The R287Q polymorphism was further reported as associated with carotid artery calcified plaque disease in European Americans [191]. Furthermore, the Lys55Arg polymorphism has been reported as a risk factor in coronary heart disease [186]. In white Americans, Lys55Arg genotype was associated with vasodilator response to bradykinin, such that forearm blood flow was significantly lower ($P = 0.043$) and forearm vascular resistance was significantly higher ($P = 0.013$) in Arg55 variant allele carriers compared to wild-type individuals. Significant associations were also observed with methacholine and sodium nitroprusside, suggesting an important role for sEH in the regulation of vascular function in humans [192]. As these are complex disease phenotypes, likely dependent on the regulation of eicosanoid metabolism that involves both cytochrome P450 epoxidation to generate the EETs as well as EPHX2 hydrolysis in the degradation of EETs, the exact genetic relationships that dictate interindividual risk differences in these disease etiologies will require an additional detailed study.

13.4.4 Regulation of Expression

Although the biological function of human EPHX2 has been extensively investigated, much less is known about the molecular mechanisms of EPHX2 regulation. Several observations in rodent models have shown that EPHX2 can be regulated by endogenous chemical mediators and some xenobiotics. For example, both cigarette smoke and γ radiation appear to affect human EPHX2 expression levels [193,194]. It has also been noted that male mice exhibit higher EPHX2 activities in liver and kidney than female mice [13]. These observations suggest that sex hormones may be involved in EPHX2 regulation, at least in mice.

In rodents, EPHX2 expression is induced by the administration of PPAR α agonists. Peroxisome proliferators are compounds that induce the size and number of hepatic peroxisomes. PPAR α agonists include clinically used hypolipidemic drugs, endogenous compounds such as steroids, dietary fatty acids, and commercial plasticizers [195]. The response to these agonists suggests that EPHX2 may play role in peroxisome proliferator-induced liver toxicity in rodents. However, whether these responses are maintained in humans is an important consideration and one that has not been definitively evaluated. To this effect, the core promoter of the human EPHX2 gene was characterized recently by the Hammock group [196]. No PPAR α responsive motifs were identifiable in the human gene's promoter region. However, nuclear factor Sp1 regulatory elements were apparent that were localized in a GC-rich region of the promoter and appear to be important contributors to the basal levels of EPHX2 transcriptional regulation.

Another recent report indicated that angiotensin II (Ang II), a potent vessel constrictor that elevates blood pressure in animal models, directly upregulates EPHX2 transcription expression mediated by an AP-1 motif present in the human EPHX2 promoter [197]. These investigators further demonstrated that the transcriptional regulation mediating EPHX2 induction by Ang II involved c-Jun/c-Fos binding to the AP-1 site at the -446 position of the gene's promoter [197]. In addition, overexpression of a mutant c-Jun protein that was lacking its respective transactivation domain markedly attenuated the EPHX2 induction response otherwise facilitated by Ang II.

Alternative splicing of RNA transcripts may also play a role in the regulation of EPHX2 expression. Interestingly, in mouse ovary, a unique variant of EPHX2 was reported as generated by alternative splicing. This variant lacked the associated phosphatase activity normally encoded in the transcript [198]. This short isoform of EPHX2 possesses an altered N-terminal sequence spliced from the second intron. Examination of the alternative splicing databases further predicts a number of potential EPHX2 splice variants in humans; however, most of these variants would be predicted not to be functional as a consequence of the deletion of entire exons or due to the introduction of stop or out-of-frame codons. To our knowledge, no publications on splice variation in human EPHX2 have been reported. This area remains to be one requiring more detailed study.

13.4.5 Summary/Pharmacological Implications

Although originally thought of as a xenobiotic-metabolizing enzyme, this is no longer considered a functional role for EPHX2. Rather, this sEH has been identified as a major contributor to the metabolism of endogenous substances, in particular, epoxides derived

from the arachidonic acid cascade. In these respects, EPHX2 appears to contribute important biological functionality in processes that include control of blood pressure and inflammatory responses. Thus, the enzyme has been targeted by pharmacological modulators, facilitated by the development of highly selective and potent inhibitors of the enzyme that are currently in clinical trials. Historically, EPHX2 represents one of the few cases where an enzyme originally described as being involved in xenobiotic metabolism has evolved as an exciting clinical target.

13.5 CONCLUSIONS

Together, the epoxide hydrolases, in particular, the microsomal (EPXH1) and soluble (EPXH2) forms of the enzyme, have achieved prominent recognition for their respective biological roles in xenobiotic and endogenous metabolism. As outlined in this chapter, these enzymes also contribute to the spectra of drug metabolism, with EPXH1 involved in the metabolism of several drug substrates and EPXH2 as a pharmacological intervention target and mediator of physiological processes such as control of blood pressure and inflammation. Although the history of discovery and characterization of these respective enzyme systems is rich, a great deal of additional study is required to fully elucidate their extended functional roles, the details of their transcriptional control, and the influence of genetic polymorphism present in these systems as potential risk modifiers in pharmacotherapy and chemically induced disease.

14.1 SUMMARY

Carboxylesterases (CESs, EC 3.1.1.1) constitute a large class of enzymes that hydrolyze chemicals containing a functional group such as a carboxylic acid ester, amide, and thioester. These enzymes are major pharmacokinetic determinants of ester/amide drugs and detoxify against organophosphorus and pyrethroid insecticides. In addition, these enzymes hydrolyze endogenous lipids and involve the assembling of lipoproteins. CESs exhibit overlapping substrate specificity; however, many drugs are hydrolyzed predominantly by a single CES. Although there are exceptions, the relative sizes between the alcohol and acyl (acid) moieties of an ester contribute significantly to the isoform-specific hydrolysis. CES activity is widely distributed in mammalian tissues, with the highest level in liver microsomes. High abundance of CES in the liver is linked to certain cellular roles, notably in directing protein trafficking. CESs belong to the superfamily of α/β -fold proteins and have similar crystal structure to other enzymes in this superfamily. CESs use a two-step mechanism for catalysis. Hydrolysis of carboxylic acid esters leads to the formation of an alcohol and a carboxylic acid. Compounds with these moieties are substrates for conjugation enzymes or transporters. Likewise, hydrolysis may create or eliminate a substrate of other phase I enzymes, particularly cytochrome P450s (CYPs). Like many other drug-metabolizing enzymes, the expression of CESs is regulated by many factors, including age, hormones, therapeutic agents,

TABLE 14.1 Primary Functions of Carboxylesterases

Function	Mechanism of Action	Example
Hydrolytic metabolism	Catalysis	Aspirin
Prodrug design	Catalysis	Oseltamivir
Mobilization of lipids	Catalysis	VDLD assembling
Detoxification	Catalysis/scavenging	Pyrethroids
Protein trafficking	Protein–protein interaction	C-reactive protein

and environmental chemicals. Mammalian species express multiple forms of CESs. However, there are notable differences in substrate specificity, tissue distribution, and regulated expression.

14.2 FUNCTIONS OF CARBOXYLESTERASES

The primary functions of CESs are to metabolize therapeutic agents [1–3], to mobilize lipids [4,5], to detoxify insecticides [6,7], and to target proteins to subcellular organelles [8,9]. While CESs act as catalytic proteins, not all the functions result directly from catalysis. As shown in Table 14.1, the catalytic action is responsible for drug metabolism and lipid mobilization but not for protein targeting. Retention of certain proteins in the endoplasmic reticulum (ER) is achieved by protein–protein interactions. CESs are known to protect against a large array of insecticides such as organophosphates and pyrethroids. The mechanisms for the detoxification vary depending on the type of insecticides. Pyrethroids, for example, are detoxified by hydrolysis. In contrast, organophosphates are detoxified by forming irreversible complexes, commonly referred to as the *scavenging mechanism*.

14.2.1 Hydrolytic Metabolism of Ester and Amide Drugs

It is estimated that 20% of drugs in the market undergo hydrolytic metabolism. These therapeutic agents contain functional groups such as carboxylic acid ester (e.g., esmolol), amide (e.g., procainamide), and thioester (e.g., spironolactone). Drugs metabolized by CESs usually have a single bond for hydrolysis, but there are exceptions such as lovastatin and spironolactone (Fig. 14.1, arrowed). In many cases, hydrolysis is a major determinant of the pharmacokinetic and pharmacodynamic behavior of ester drugs. For example, metoprolol and its ester analog esmolol are both β 1-selective adrenergic antagonists and widely used for cardiovascular disorders (e.g., cardiac arrhythmia). In contrast to metoprolol, esmolol is rapidly hydrolyzed by CESs and has a very short duration of action [10]. Therefore, esmolol is administered intravenously and used in critically ill patients who need a quick but short β 1-blockade therapy. In contrast, metoprolol is usually administered orally and used for chronic disorders.

Likewise, the hydrolytic rate of ester and amide analogs is a major determinant for therapeutic use. Although both carboxylic acid and amide bonds can be hydrolyzed by CESs, the hydrolysis of amide bonds usually proceeds slower than that of carboxylic acid esters. As a result, an ester drug and its amide counterpart are used for different

Figure 14.1 Chemical structure of representative drugs metabolized by carboxylesterases. The chemical bonds hydrolyzed by carboxylesterases are marked with an arrow.

indications. For example, procaine is hydrolyzed much faster than its amide counterpart procainamide [11]. Thus, procaine is used as a local anesthetic and has no systemic application. In contrast, procainamide reaches the systematic circulation and is used to treat cardiac arrhythmia. Consistent with the hydrolysis of amide bonds, CESs catalyze deamination. Rufinamide, a recently approved compound for Lennox–Gastaut syndrome (a special type of seizure), undergoes exclusively deamination [12].

In addition to hydrolysis, certain CESs are known to catalyze transesterification. For example, the antiplatelet agent clopidogrel, a methyl ester, normally undergoes rapid hydrolysis [13]. In the presence of ethyl alcohol, substantial amount of clopidogrel is converted to the corresponding ethyl ester, ethyl-clopidogrel (Fig. 14.2). The formation of ethyl-clopidogrel likely enhances the therapeutic activity of clopidogrel as hydrolysis of clopidogrel represents inactivation of this antiplatelet agent [14,15]. On the other hand, ethyl-clopidogrel is structurally similar to clopidogrel and presumably undergoes

Figure 14.2 Transesterification of clopidogrel CES1 normally hydrolyzes clopidogrel. In the presence of ethyl alcohol, however, this enzyme catalyzes the formation of ethyl-clopidogrel.

similar oxidative activation [3]. Importantly, epidemiological analysis has shown that one-third of patients on clopidogrel drink alcohol [16], and these patients may have extended therapeutic effect. However, it remains to be determined to which extent the transesterification takes place in patients who are on clopidogrel and also drink alcohol.

14.2.2 Hydrolysis-Based Drug Design

CESs have a wide tissue distribution, and more importantly, these enzymes, compared with other enzymatic systems, have a high catalytic efficiency. Therefore, the CES system is widely incorporated into strategies for prodrug design [17,18]. One of the major advantages of ester prodrugs is to drastically increase the bioavailability [18]. For example, oseltamivir, an anti-influenza viral agent, has almost 80% bioavailability [19]. In contrast, its hydrolytic metabolite, although a potent inhibitor of the neuraminidase of the influenza virus, has an oral availability of 4% only [19]. In some other cases, ester prodrugs have much lower toxicity. For example, capecitabine, an ester prodrug of anticancer agent 5-fluorouracil, shows much lower intestinal toxicity than the therapeutically active compound [20]. To achieve tissue-specific activation, targeted expression of a prodrug CES has been tested through gene-delivery system [21].

14.2.3 Mobilization of Lipids

Many CESs are shown to hydrolyze lipid compounds such as choline esters, fatty acyl-CoAs, acylcarnitines, acylglycerols, phospholipids, retinyl esters, and cholesteryl esters [22–26]. Hydrolysis followed by re-esterification with different acyl moieties provides an important mechanism for generation of structurally diversified esters *in vivo*. CES-mediated action likely plays an essential role in the transportation and uptake of certain acyl esters or amides [24,25]. For example, very low density lipoprotein (VLDL) particles, a major delivery system of lipids from the liver to the periphery system, are assembled in and secreted by the liver. Assembling of these particles requires hydrolysis and re-esterification of triacylglycerol in the hepatic storage pool. Cells (e.g., RH7777 hepatoma line) lacking a CES called *triacylglycerol hydrolase* fail to assemble and secrete VLDL particles. Transfection of these cells with a cDNA encoding this CES causes a rapid depletion of intracellular triacylglycerol and a marked increase in the secretion of VLDL particles [26].

The importance of this CES in the mobilization of lipids has been recently confirmed by the knockout mouse model [4]. Consistent with a role of this CES in the assembling of VLDL, knockout mice show attenuated secretion of VLDL. Interestingly, the hepatic triacylglycerol level is not increased in the knockouts. Instead, the respiratory quotient and energy expenditure are increased. In addition, insulin sensitivity and glucose tolerance are improved in these knockouts. In humans, a role of CESs in the mobilization of lipids has also been implicated. CES1, a functionally related enzyme to the mouse CES, is abundantly expressed in human adipose tissues [27]. Inhibition of this CES in monocytes and macrophages increases the retention of intracellular lipids and enhances the development of the foamy phenotype [28]. Foamy macrophages are closely associated with the development of atherosclerosis, the major risk factor for cardiac and vascular diseases. Likewise, transgenic expression of CES1 leads to a more proatherogenic plasma lipid and apoB profile [29]. Apparently, further studies are required to determine the exact nature of CESs in the catabolism of lipids.

14.2.4 Detoxification of Insecticides

CESs, on the other hand, are also known to play important roles in detoxifying xenobiotics, particularly organophosphorus, carbamate, and pyrethroid insecticides [30–35]. These compounds constitute more than 80% total insecticides in the global use, including agriculture, residential setting, parasite eradication, and public facility. Animal studies demonstrate that inhibition of CES activity potentiates the toxicity of many organophosphates [34]. Intravenous administration of purified CESs affords considerable protection against the toxicity of soman, sarin, and paraoxon, providing direct evidence that CESs protect against chemical warfare agents and organophosphorus insecticides [36]. Similarly, CES activity is directly related to the toxicity of pyrethroid insecticides. For example, neonatal rats express only 10–15% of hepatic CESs of adult rats and exhibit a 16-fold greater sensitivity to pyrethroid deltamethrin [37]. More importantly, the relative insensitivity of adult rats is attenuated by pretreatment with tri-*o*-tolyl phosphate, a potent CES inhibitor.

The mechanisms of detoxification vary depending on the type of insecticides. CESs interact stoichiometrically and irreversibly with organophosphate [38]. Such an interaction is analogous to that between organophosphate and acetylcholinesterase, a vital enzyme that terminates neurotransmission of acetylcholine [38–40]. Interaction with CESs decreases the amount of organophosphate, which would otherwise inhibit acetylcholinesterase. Therefore, CESs detoxify organophosphates by acting as scavenging molecules. In contrast, CESs detoxify carbamates and pyrethroids by hydrolysis [41–47]. Another important difference is their insecticidal targets. As discussed above, organophosphorus insecticides (carbamate as well) target acetylcholinesterase. In contrast, pyrethroids target ion channels, particularly voltage-dependent sodium channels [48]. Such distinction provides a molecular basis for combined use of organophosphates and pyrethroids. Currently, there are hundreds even thousands of insecticide mixtures containing these two types of insecticides in the market [49]. The combined use is particularly effective against insecticide-resistant strains [50–52]. But at the same time, the toxicity to humans and other unintended species is presumably increased as well. While hydrolysis is generally considered to be detoxification, in some cases, a hydrolytic metabolite is more toxic than its parent compound. For example, hydrolysis of dehydropyrrolizidine alkaloids by CESs produces reactive dehydronecines, which form DNA/protein adducts and induce cell injury [53].

14.2.5 Protein Trafficking

High abundance of CESs in the liver is linked to certain cellular roles, notably in directing protein trafficking [8,9]. For example, two rabbit microsomal CESs have been shown to interact with and regulate the secretion of C-reactive protein [9], which is rapidly increased in the blood during the acute-phase response. Such a rapid release is likely from the C-reactive protein pool normally retained by interacting with microsomal CESs. The interaction is mediated by residues from 477 to 497 in the CESs. Interestingly, the interaction with C-reactive protein does not diminish the hydrolytic activity [9].

In contrast, β -glucuronidase interacts with CESs through their catalytically active site, thus leading to significant reduction or elimination in the CES activity [8,54]. Like C-reactive protein, the interaction of β -glucuronidase with microsomal CESs

results in the sequestration of β -glucuronidase in the ER [5,6], which is otherwise targeted to the lysosome. The microsomal β -glucuronidase has been shown to hydrolyze glucuronidated hormones (e.g., steroids), thus providing an effective mechanism that recycles physiologically important molecules [54]. Given the fact that CESs interact with β -glucuronidase through the active site, this interaction can be modulated by CES substrates and inhibitors [55]. It has been reported that administration of the anticancer agent irinotecan or exposure to organophosphates increases serum β -glucuronidase [56,57]. Irinotecan is a substrate of CESs, whereas organophosphates are potent inhibitors of these enzymes.

14.3 CLASSIFICATION AND STRUCTURAL FEATURES

Mammalian CESs are classified based on the sequence identity of amino acids [1,58,59]. CESs are all translated as secretory proteins; however, the majority of CESs are retained in the ER [60]. Secretory CESs are glycosylated to a much greater extent [61–63]. All CESs, even with less sequence identity, have the core segments arranged as alternate α -helix and β -sheets connected by loops with a varying length [40]. The crystal structure of CESs shows that these enzymes have three functional domains: the central catalytic domain surrounded by the $\alpha\beta$ -domain and regulatory domain [64,65]. Like acetylcholinesterase, the catalytic machinery is located at the bottom of the catalytic gorge [64–66].

14.3.1 Classification Methods

Several methods have been used to classify CESs. Early classification was based on the substrate specificity [67]. This approach soon became unsatisfactory because these enzymes have broad and overlapping substrate specificities. Classification was later made based on isoelectrophoretic points (IPs) [68]. This approach, although more definitive in terms of linking to individual CESs, was unsatisfactory because the same CES may have different IPs due to protein aggregation or differences in glycosylation. In addition, it is difficult to make a direct connection between the catalytic function (substrate specificity) and a CES based on its IPs. Currently, classification of CESs is made according to sequence identity of CES proteins. In this system, all mammalian CESs (e.g., human and rodents) are taken into consideration [2]. Members in the same family have a sequence identity of 60% or higher, otherwise, a different family is assigned. According to this method, six families are created: CES1, CES2, CES3, CES4, CES5, and CES6. The CES1 family contains the largest number of CESs and has eight subfamilies [2].

14.3.2 Salient Features of Carboxylesterases

Mammalian CESs have several salient structural features. These enzymes are synthesized as a large precursor with an N-terminal cleavable signal peptide [61–63]. Normally, this peptide directs newly translated proteins into the lumen of the ER for secretion. On translocation, this signal peptide is usually cleaved. However, many CESs are retained in the ER. These ER CESs have a C-terminal tetrapeptide HXEL. This consensus sequence is sufficient to keep a protein from being secreted [61–63]. In addition,

CESs are glycoproteins and secretory CESs are glycosylated to a much greater extent [62,63]. The extensive glycosylation of serum CESs suggests that glycosylation facilitates the secretory process and increases solubility. Another important posttranslational modification of CESs is the formation of disulfide bonds. All mammalian CESs contain at least four cysteines [2,69]; therefore, each CES has two or probably more disulfide bonds. Surprisingly, disruption of the disulfide bonds by reducing agents causes little changes in the catalytic activity toward 1-naphthylacetate, although reduced CESs are less compact than the native enzymes. On the basis of folding and refolding studies, it appears that the formation of the disulfide bonds plays critical roles in folding CESs into a catalytically active conformation [69].

14.3.3 Secondary and Crystal Structure

In addition to many salient structural features, CESs exhibit a unique assembly on the secondary structure. The core segments of CESs are arranged as alternate α -helix and β -sheets connected by loops with a varying length [40]. Such unique arrangements place CESs into the superfamily of proteins commonly referred to as the *α/β -hydrolase fold proteins*. Some members in this superfamily such as acetylcholinesterase are highly related to CESs in terms of the sequence identity and functions. On the other hand, some members such as neuroligin share little sequence identity with CESs and act as noncatalytic proteins [40].

Consistent with the similarity in the secondary structure, CESs share crystal structure with members of the α/β -hydrolase fold enzymes such as acetylcholinesterase and cholesterol esterase [64–66]. Overall, CESs have three functional domains: the central catalytic domain surrounded by the $\alpha\beta$ -domain and the regulatory domain. Like other members, CESs have the catalytic triad located at the base of a deep catalytic gorge. On the other hand, CESs show some important differences. For example, human CES1 has two substrate binding pockets: one is small and rigid and the other is large and flexible [65]. It has been proposed that the small/rigid pocket provides selectivity, whereas the large/flexible pocket is promiscuous. Interestingly, the sequence forming the small/rigid pocket is much more conserved than the sequence forming the large/flexible pocket. Even between CESs, notable differences exist. For example, an N-linked glycosylation chain is located at the product exit in a rabbit CES but not in human CES1 [64,65]. This carbohydrate chain presumably enhances catalysis by facilitating product exit. Furthermore, human CES1 exists as trimer or hexamer, whereas the rabbit enzyme exists as a monomer. The formation of the multimers of CES1 is likely due to the presence of a Z-shaped dimer interface [65].

14.3.4 Human Carboxylesterases

Like other mammalian species, humans express multiple forms of CESs. On the basis of molecular cloning and bioinformatics study, there are seven distinct CES genes in the human genome [1,58,59]. These genes are assigned to the CES1, CES2, CES3, CES5, and CES6 families, respectively. The CES1 family has three members, including CES1A1, CES1A2, and CES1A3. As described below, CES1A2 is an alternative form of CES1A3; thus, humans may express CES1A2 or CES1A3 but not both. All human CESs show a sequence identity of 39–44% [58,59]. The salient features of human CESs are shown in Fig. 14.3.

Figure 14.3 Salient features of human carboxylesterases. The protein sequences of carboxylesterases are derived from the corresponding cDNAs with the following accession numbers: NM_001025195 for CES1, NM_003869 for CES2, NM_024922 for CES3, NM_145024 for CES5, and FLJ37464 for CES6.

14.3.4.1 CES1 Family. Among the three CES1 members, only the *CES1A1* and *CES1A2* genes encode functional proteins [70,71]. The *CES1A3* gene, formerly termed CES1A4, has a premature stop codon thus is considered a pseudogene [72]. The *CES1A1* and *CES1A2* proteins differ by only four amino acids and these residues are located in the signal peptide. Therefore, these genes actually encode identical mature CESs. A recent study by analyzing a large number of individual samples has revealed that the *CES1A2* gene is a variant of the *CES1A3* gene [70]. Interestingly, the percentage of population carrying the *CES1A2* gene varies markedly depending on an ethnic group. African-Americans have the least percentage (5.1%), Japanese population has the highest percentage (31.3%), and Caucasians have 14%. In addition, a *CES1A1* variant exists and has the first exon converted from the corresponding exon of the *CES1A3* gene. Therefore, a total of four haplotypes of CESs can occur based on various CES1 genes: (i) *CES1A1* and *CES1A3*, (ii) *CES1A1* and *CES1A2*, (iii) *CES1A1* variant and *CES1A3*, and (iv) *CES1A1* variant and *CES1A2*. All CES1 genes are clustered at position 16q12.2, and the *CES1A1* gene has an orientation opposite to the *CES1A2* and the *CES1A3* gene. In addition, the *CES1A* genes produce alternatively splicing variants, leading to the deletion of Ala-18 and Gln-362 [73]. It remains to

be determined whether the splicing variants are derived from the *CES1A1* or *CES1A2* gene. Nevertheless, the deletion variants consistently have lower activity [1].

14.3.4.2 *CES2 Family.* In contrast to the CES1 family, humans have only a single member in this family [1]. This gene is located at 16q22.1, a second cluster of CES genes in the human genome. Like the *CES1A2* and *CES1A3* genes, the CES2 gene has the orientation opposite to that of the *CES1A1* gene. The CES2 gene uses three alternative promoters for transcriptions, and the relative activities of these promoters differ depending on a tissue [74]. Like the CES1 gene, the CES2 gene produces alternative splicing transcripts [1]. Several CES2 splicing variants share a 16 amino acid deletion, which occurs in exon 10. This deletion produces catalytically inactive protein. In addition, alternative use of the translation initiation codon leads to the addition of extra 64 amino acid to the N-terminus, although it remains to be determined whether such addition alters the hydrolytic activity and to which extent the alternative codon is used for translation initiation. Consistent with multiple alternative variants, multiple CES2 transcripts with marked differences in length have been identified [1].

14.3.4.3 *CES3 Family.* The human CES3 gene is clustered with the CES2 gene and has the same orientation in the genome as well [1,75]. Like the CES2 gene, multiple CES3 transcripts are identified with one being 2.1 kb and the other being 3.9 kb. These two transcripts differ in the 3'-untranslated region by 1750 bp. An alternative splicing variant in exon 12 was reported and this variant has a nine amino acid deletion (residues 481–483). Compared with CES1 and CES2, CES3 has a restricted tissue expression pattern. According to Northern blotting analysis, high level of CES3 mRNA is present in the liver, colon, and to a significantly less extent in the small intestine [75]. On the basis of a database of expressed sequence tags (ESTs) [1], the CES3 transcripts are also present in the trachea and placenta. However, it is not clear whether the EST transcripts are translated into protein. CES3 is much less active toward various commonly used substrates. On the basis of the catalytic efficiency on the hydrolysis of irinotecan, CES3 is 5 times less active than CES1 and 500 times less active than CES2 [75].

14.3.4.4 *CES5 Family.* Like the CES2 and CES3 families, the CES5 family has only a single member in humans [58]. The CES encoded by this gene is called *cauxin*, commonly referred to as *CES-like urinary excreted protein*. This protein is abundantly present in the urine of male animals such as cats, dogs, and sheep. It has been postulated that this CES is involved in the production of felinine, a precursor of the putative cat pheromone hormone. Nevertheless, the presence of this protein in the urine of humans remains to be established. However, an EST database shows that human CES5 is expressed in the brain, thymus, and testis. Like the *CES1A1* gene, the human CES5 gene is located at 16q22.1, the first cluster of CES genes in the human genome. Compared with CES1, CES2, and CES3, human CES5 has several unique features, notably in the ER retention consensus sequence, the potential N-linked glycosylation sites, and the charge clamp residues. CES5 lacks the C-terminal ER retention tetrapeptide, consistent with the fact that cauxin is a secretory protein. Additionally, CES5 has four putative N-linked glycosylation sites, the most among human CESs [58]. Coincidentally, several rodent serum CESs are highly glycosylated as well. And finally, CES5 does not have the conserved charge clamp residues. In CES1, these residues contribute to oligomerization [65].

14.3.4.5 CES6 Family. Human CES6 is a putative CES based on the sequence alignment analyses against the human genome. This putative enzyme has key residues involved in catalysis, formation of intramolecular disulfide bonds, oligomerization, and regulation of catalysis [59]. On the other hand, CES6 exhibits several major differences compared with CES1, CES2, and CES3. This CES lacks the ER retention tetrapeptide and has three potential N-linked glycosylation sites. These characteristics are consistent with the possibility of being a secretory CES. Like other CESs, CES6 variants exist due to alternative splicing. On the basis of reported ESTs, the CES6 gene is expressed in a broad range of tissues, including the skin, brain, lung, kidney, and placenta. The CES6 gene is clustered with the CES2 and CES3 genes with the same orientation in the genome.

14.4 CATALYTIC MECHANISM, SUBSTRATE SPECIFICITY, ACTIVATORS, AND INHIBITORS

As described above, CESs have a catalytic triad and use a two-step reaction mechanism for the catalysis [1–3]. In the past decade, tremendous progress has been made on the substrate specificity of CESs, particularly CES1 and CES2 [1–3,32,76]. It appears that both CESs, although with broad substrate specificity, show a strong structural preference for hydrolysis. CES1 preferably hydrolyzes esters with a relatively large acyl moiety, whereas the opposite is true with CES2. The catalytic activity of CESs can be enhanced by activators such as pinacolone [77] and inhibited by compounds such as benzil and trifluoromethyl ketone (TFK) derivatives [78–83].

14.4.1 Mechanism of Catalysis

CESs, like other esterases, use a two-step reaction mechanism for hydrolysis centered by the “catalytic triad.” This triad is made of the nucleophile (serine), the base (histidine), and the acid (glutamate) [2,64–67]. The first step of the reaction involves the attack of the nucleophile serine on the carbonyl carbon of a substrate, resulting in the release of the alcohol moiety from the substrate and simultaneously forming a covalent linkage between the remaining acid moiety of the substrate and the enzyme. Subsequently, the covalent linkage is cleaved through a water molecule activated by the base histidine, leading to the release of the acyl moiety of the substrate accompanied by the regeneration of the enzyme (Fig. 14.4).

The two-step hydrolysis mechanism, on the other hand, provides a molecular explanation to the toxicity of organophosphorus compounds. These insecticides, usually called *hemi-substrates*, interact similarly as true substrates. However, the resultant organophosphate–enzyme complex creates a steric exclusion, which prevents the second nucleophilic attack mediated by the activated water molecule [84]. Apparently, interaction with acetylcholinesterase represents toxicity, whereas interaction with CESs is considered detoxification against organophosphorus compounds.

14.4.2 Substrate Specificity of Human CES1 and CES2

CESs generally have high catalytic efficiency. This is particularly true with short-chain standard substrates such as *para*-nitrophenylacetate. Hydrolase A, a rat CES,

Figure 14.4 Catalytic cycle of carboxylesterases.

hydrolyzes this ester at a $K_{\text{cat}}/K_{\text{M}}$ ratio of $\sim 10^7 \text{ M}^{-1} \text{ s}^{-1}$. This rate of efficiency is close to the diffusion rate of this ester, a measure of being a perfect enzyme. However, there are some exceptions for this general observation [60]. For example, human CES3 shows little hydrolytic activity toward this ester. As a matter of fact, human CES3 remains to be characterized for its preferable substrates.

Human CES1 and CES2, on the other hand, have been well characterized for their substrate specificity [1,2,13,85]. As described above, the hydrolytic preference of CES1 and CES2 is likely related to the sizes of the acyl and alcohol moieties of esters. On the basis of the molecular weights, the acyl moiety (clopidogrel carboxylate) of clopidogrel is 10 times as big as the alcohol moiety (methanol); therefore, this antiplatelet agent is hydrolyzed by CES1 but not CES2 (Fig. 14.5). Conversely, the acyl moiety of irinotecan is much smaller than the alcohol moiety; thus, this anticancer agent is predominately hydrolyzed by CES2. The alcohol/acyl size-based preference can apply to compounds with multiple ester bonds as well. Psychomotor stimulant cocaine, for example, contains two ester bonds and complete hydrolysis produces ecgonine, methanol, and benzoic acid. Among these products, ecgonine is the largest and acts as the acyl moiety relatively to methanol but the alcohol moiety relatively to benzoic acid. Consistent with the alcohol/acyl-based preference, CES1 hydrolyzes ecgonine-methyl ester, whereas CES2 benzoate-ecgoninyl ester [86,87]. Figure 14.5 shows several drugs that are selectively hydrolyzed by CES1 or CES2.

While the relative size of the acyl and alcohol moieties is a major determinant in the hydrolytic preference between CES1 and CES2, there are notable exceptions. For example, illicit heroine contains two ester bonds with both sharing the alcohol moiety [65] (Fig. 14.6). This alcohol moiety is much bigger than the acids in both cases. Interestingly, both ester bonds are preferably hydrolyzed by CES1 but not CES2. Although the crystal structure of CES2 remains to be elucidated, CES1 has a large/flexible substrate pocket, which accommodates bulky moiety of either alcohol or acid group. Such a unique structure likely contributes to the preferable hydrolysis of heroin by CES1 [6]. On the other hand, the *cis* and *trans* conformers of permethrin, even with the same sizes of acyl and alcohol moieties, are hydrolyzed differentially. For example, *trans*-permethrin is hydrolyzed comparably by both CES1 and CES2, but the *cis*-conformer is hydrolyzed by CES2 to a much greater extent than CES1 [6].

Figure 14.5 Substrate preference between human carboxylesterases CES1 and CES2. Drugs containing smaller alcohol moiety (boxed) are hydrolyzed by CES1 (left) and those containing larger alcohol moiety are hydrolyzed by CES2 (right).

14.4.3 Activators and Inhibitors

Like many other enzyme systems, the activity of CESs can be enhanced or inhibited. While the inhibition has been extensively studied, little information is known on the activation. Several chemicals such as pinacolone and pinacolyl alcohol have been shown to increase the hydrolytic activity of CESs. Enhancement has been observed *in vitro* and *in vivo* with pinacolone and pinacolyl alcohol [77]. These chemicals are metabolites of soman, a potent and irreversible inhibitor of serine enzymes, including CESs. The precise mechanism remains to be elucidated for the enhanced hydrolytic activity. Interestingly, commonly used solvent acetone also enhances hydrolytic activity of CESs [77], pointing to a possible mechanism of improving the accessibility of enzymes to a substrate.

In contrast to activation, several types of inhibitions are synthesized and well characterized. Ester drugs hydrolyzed by the same CESs may function as competitive

Figure 14.6 Examples of preferable hydrolysis independently of the relative sizes of the acyl/alcohol moieties. Boxed are the alcohol moieties of various esters. The two isomers of permethrin share the alcohol moiety, so do the two esters of heroine.

inhibitors toward each other. As described above, both clopidogrel and oseltamivir are substrates of CES1 with the former being kinetically favorable [76]. As a result, clopidogrel inhibits the hydrolysis of oseltamivir by as much as 90% when the same concentrations are used. The first-pass hydrolysis accounts for 90% of total oseltamivir activation [87–89], presumably due to the initial high concentration in the liver. Co-administration of clopidogrel inhibits the first-pass activation of oseltamivir and likely attenuates the activation of oseltamivir.

The second type of inhibition is achieved by chemicals that irreversibly modify the active-site serine residues, so-called serine enzyme inhibitors. In addition to organophosphorus insecticides, several irreversible inhibitors of serine enzymes are well characterized, including phenylmethylsulfonyl fluoride (PMSF) and inorganic salts such as sodium fluoride [60]. While these inhibitors generally act nonspecifically among serine enzymes, the IC_{50} values can vary markedly from one CES to another. For example, rat CES hydrolase A is ~ 1000 times more sensitive than hydrolase B based on the IC_{50} values (100 nM vs 100 μ M) [60]. Some chemicals such as malathion can function as inhibitors and substrates. This organophosphorothioate (OPT) contains a

Figure 14.7 An example of substrate-inhibitor switch. Malathion is a substrate of carboxylesterases but can be a potent inhibitor on conversion to the corresponding oxon by multiple cytochrome P450s (CYP).

P=S bond and two carboxylic acid bonds (Fig. 14.7). Oxidative desulfuration of OPTs results in the formation of a P=O bond, the corresponding oxon. The oxon is an irreversible inhibitor of CESs. The carboxylic acid bonds, on the other hand, are subjected to hydrolysis by CESs. Hydrolytic metabolism of malathion represents detoxification (inactivation) and is correlated well with the abundance of CES1 in humans [90].

Two classes of compounds, with a potential of clinical use, are well characterized for the inhibition of CESs [78–83,91] (Fig. 14.8). Benzil derivatives belong to one of the classes and TFK-containing analogs belong to the other. Both benzil and TFK compounds inhibit catalysis of CESs by acting on the active-site residue serine. Compounds with this type of inhibition are called *transitional analog inhibitors*, and the inhibition is reversible. Among TFK compounds, thioether analogs are more potent than their sulfinyl or sulfonyl counterparts [82]. This is more evident with prolonged preincubation. The precise mechanism behind their different potency remains to be determined. It has been postulated that these substitution moieties may vary in supporting the

Figure 14.8 Selective inhibitors of CES1 and CES2. Data were compiled based on previous reports by Hicks *et al.* [79] on phenylene-benzene-sulfonamide, Hyatt *et al.* [81] on bromophenyl-dione and dithien-ylethane-dione [83], and Wadkins *et al.* on dofacylthio-trifluoropropane [62]. The K_i values (nM) for AchE (human acetylcholinesterase) and BChE (human butyrylcholinesterase) are shown for comparison. ND, not determined.

equilibrium between the ketone and *gem*-diol forms of a TKF compound. The ketone form is more inhibitory. Another interesting phenomenon with TFK compounds is their selectivity on acetylcholinesterase and butyrylcholinesterase. Many TFK compounds efficaciously inhibit CESs but surprisingly have little inhibition against cholinesterases (Fig. 14.8). This is interesting because CESs are highly related to cholinesterases in terms of the overall crystal structures and the sequence identity. On the other hand, TFK compounds show only some selectivity in inhibiting various CESs. For example, human CES1 and CES2 are comparably inhibited by a panel of TFK compounds [82]. Dofacylthio-trifluoropropane, the highest selectivity in this panel, exhibits only a five-fold difference in the inhibitory potency between CES1 and CES2 based on the K_i values (Fig. 14.8).

Benzil derivatives, in contrast, show much higher selectivity on the inhibition of various CESs [79,80]. These compounds, with a common feature of bulky structure, were initially synthesized for selective inhibition of CES2 to minimize the intestinal side effect (diarrhea) of irinotecan. Recently, structurally related compounds have been synthesized to contain an indole-dione or a sulfonamide [79,81] (Fig. 14.8). These compounds have shown improved selectivity with enhanced potency. For example,

dithienyl ethane-dione is ~20 times more potent in the inhibition of CES1 than CES2 (Fig. 14.8). Conversely, phenylene-chlorobenzenesulfonamide inhibits CES2 with a K_i value of 41 nM, three magnitudes lower than that on CES1 (Fig. 14.8). Actually, a panel of benzene sulfonamides tested shows little inhibition on CES1, although they all efficaciously inhibit CES2 [79]. The highly selective inhibitors are bulky in shape, and such bulky structure likely presents greater steric effect than TFK compounds. Apparently, combination of steric bulky structure with TFK compounds will likely produce more selective and potent inhibitors [80]. As described above, these compounds are transitional analog inhibitors; thus, they have hypothetical sizes of the alcohol and acyl moieties as seen in the substrates. Likewise, the hypothetical sizes are associated with the relative potency of inhibiting CES1 and CES2.

14.5 EXPRESSION AND REGULATION

In mammalian species, CES activity has a broad tissue distribution with the highest level in the liver. The expression of CESs is regulated by many factors, including age, hormones, pharmaceutical agents, environmental chemicals, and disease status [92–97]. Induction of CESs is generally minimal or moderate [93,94], whereas suppression can be profound [96]. On the basis of *in vitro* and clinical studies, both induction and suppression may significantly alter the metabolisms of ester/amide drugs and have severe clinical consequences.

14.5.1 Tissue Distribution of Human Carboxylesterases

CESs are generally present in a wide range of tissues and cells. However, the expression level varies markedly depending on a CES and also a tissue. Several experimental approaches have been used to determine the expression of various CESs, particularly CES1, CES2, and CES3 [75,92,94,96,98]. These methods include reverse transcription-quantitative PCR and Northern and Western blotting. Owing to intrinsic differences among these methods, the magnitude of differences in the expression levels may vary from one method to another method. Discrepancy can also rise from one laboratory to another. Nevertheless, there is a general agreement in all the reported data.

The expression level of CES1, CES2, and CES3 is summarized in Table 14.2. This represents composite data from various laboratories, therefore, plus or minus signs are used to reflect the relative levels. As expected, the liver expresses the highest level of all three CESs. Among them, CES3 has the most restricted tissue expression [1,75]. In addition to the liver, CES1 is also expressed at high levels in esophagus, larynx, and lung [1]. In contrast, CES2 is highly expressed in the intestine and kidney [1,98]. The intestine (colon) also contains high levels of CES3 [1,75]. The expression patterns suggest that CES2 has a dominant role in xenobiotic elimination, whereas CES1 is involved in the metabolism of both endo- and xenobiotics.

14.5.2 Ontogenic Expression

The hepatic expression of CES1 and CES2 shows an age-dependent expression. Overall, the adults express the highest level of CES1 and CES2 mRNA, pediatric donors express less CES1 and CES2 but fetal donors express the least level for both enzymes

TABLE 14.2 Levels of CES1, CES2, and CES3 in Various Tissues

Tissue	CES1	CES2	CES3
Adipose	++	++	—
Adrenal	+	++	—
Brain	+	—	—
Esophagus	++	+	—
Heart	+	+	—
Intestine	+	+++	+++
Kidney	+	++	—

TABLE 14.3 Relative mRNA Levels of Carboxylesterases HCE1 and HCE2 in Fetuses, Children (0–10 Years Old), and Adults (≥18 Years)

Group	<i>n</i>	Minimum	Maximum	Variability	Mean	CV (%)
Fetus-HCE1	48	0.07	30.15	431 (fold)	3.32	172
Child-HCE1	34	12.18	2657.77	218	711.47	90
Adult-HCE1	22	225.50	2659.61	12	1059.59	61
Fetus-HCE2	48	0.20	4.28	21	1.63	91
Child-HCE2	34	7.00	148.78	21	65.82	53
Adult-HCE2	22	39.89	168.66	4	89.87	39

[92]. On the basis of the values of the means, the adult group has CES1 at levels 319-fold higher than the fetal group and ~50% higher than the child group (Table 14.3). Likewise, the adult group expresses CES2 at levels 55-fold higher than the fetal group and ~40% higher than the child group. In addition to the large difference among various age groups (intergroup), there is a large interindividual variability within a group. Interestingly, interindividual variability is inversely correlated with age. The fetal group, for example, has a 431-fold difference (ratio between the maximum and the minimum) in CES1 mRNA with a coefficient of variation (CV) of as high as 172% (Table 14.3). The pediatric and adult groups, on the other hand, vary less in CES1 mRNA with a 218- and 12-fold difference, respectively (Table 14.3). The inverse relationship of interindividual variability with age suggests that both developmental and xenobiotic regulations are involved in fetal and pediatric individuals. In contrast, the expression of CESs in adults is regulated by nondevelopmental factors only.

14.5.3 Induction of CES1 and CES2

CESs, like many other enzymes, can be induced by endogenous factors and xenobiotics. However, the induction is minimal or moderate at the most, presumably due

to high level of basal expression [93,94]. In hepatic cell lines, several antioxidants are shown to increase the expression of CES1A1 [99]. The induction is achieved by the transcription factor Nrf2. Interestingly, these antioxidants cause little induction of CES1A2, although the CES1A1 and CES1A2 genes are highly similar. In primary hepatocytes, several prototypical types of CYP inducers such as rifampicin, phenobarbital, and dexamethasone increase the expression of CES1 and CES2 by 20–50% at the protein level and ~80% at the level of mRNA [85,93,94]. The induction, although moderate, may have clinical implications. For example, coadministration of phenobarbital has been shown to markedly increase the hydrolysis of rufinamide, a recently approved antiepileptic by the US Food and Drug Administration. As a result, the steady-state plasma concentration of rufinamide decreases by as much as 46% [12]. The decrease is the most profound in children, pointing to the possibility that CESs are more inducible during the developmental stage. Phenytoin but not topiramate increases the hydrolysis of rufinamide as well [12]. Like phenobarbital, phenytoin is a potent activator of the constitutive androstane receptor [85,100]. These findings suggest that phenobarbital-type inducers may cause CES-based interaction, particularly in children.

14.5.4 Suppression of CES1 and CES2

It has been reported that hydrolytic biotransformation is decreased in patients with liver conditions such as hepatitis and cirrhosis [101–103]. In these conditions, the production of various proinflammatory cytokines (e.g., IL-6) is markedly increased [104–106]. In support of the role of cytokines in the reduced hydrolysis, IL-6 suppresses the expression of both CES1 and CES2 in primary hepatocytes [96]. The suppression is achieved primarily by transrepression as this cytokine decreases the activity of both CES1A2 and CES2 promoters. It appears that IL-6 represses the CES1A2 promoter through the upstream sequence located from -8251 to -7851.

The potential clinical significance of IL-6-suppressed expression of CESs is illustrated by inversely altering the cytotoxicity in response to ester drugs, including clopidogrel, irinotecan, and anti-influenza viral agent oseltamivir [13,76,96]. Hydrolysis of clopidogrel represents detoxification, whereas hydrolysis of irinotecan and oseltamivir increases cytotoxicity. As shown in Fig. 14.9, cells pretreated with IL-6 are spread and the projects are well extended when exposed to oseltamivir (right, top of Fig. 14.9). In contrast, cells without IL-6 pretreatment are rounded, isolated, and swollen with the presence of vesicles in the cytoplasm (left, top of Fig. 14.9). Conversely, when exposed to clopidogrel, cells pretreated with IL-6 exhibit profound morphological changes (e.g., aggregation), whereas cells without IL-6 pretreatment show normal appearance (middle of Fig. 14.9). As for irinotecan, cells without IL-6 pretreatment are isolated and shrank, whereas cells pretreated with IL-6 are morphologically normal (bottom of Fig. 14.9). The observed changes are opposite to the changes in cells in which CESs are overexpressed [13,76,107].

14.6 PHARMACOGENOMICS OF CARBOXYLESTERASES

Pharmacogenomics of CESs deals with several issues from altered hydrolysis in certain individuals to potential interactions with other drug elimination systems. Single nucleotide polymorphisms (SNPs) are increasingly identified in CES genes [1], and

Figure 14.9 Morphological changes induced by interleukin-6 (IL-6) in response to oseltamivir, clopidogrel, and irinotecan HepG2 cells were seeded into 96-well plates at a density of 5000/well. After an overnight incubation, IL-6 (50 ng/mL) in 1% serum medium was added to half of the wells, and the treatment lasted for 12 h. Thereafter, the cells were washed with culture medium twice and treated with oseltamivir (100 μ M), clopidogrel (100 μ M), or irinotecan (3 μ M) in full-medium. The drug-medium was replaced with fresh drug-containing medium at 24 h. After an additional 24-h incubation, images were taken under bright field ($\times 250$).

some of them have been linked to poor clinical outcomes [108–114]. On the other hand, hydrolysis of carboxylic acid esters by CESs leads to the formation of products with an alcohol and a carboxylic acid. These functional groups can undergo further metabolism, notably conjugation reactions [115]. In addition, the carboxylic acid is negatively charged and elimination of the acid is likely achieved by transporters, presenting another possible interaction [116,117].

14.6.1 Polymorphisms

It has been shown that CES-based hydrolysis exhibits a large interindividual variability, particularly when population from various age is considered. As described above,

many factors such as hormones and xenobiotic exposure may alter the expression and contribute to individual variation in hydrolysis. On the other hand, genetic variation is increasingly recognized as an important contributor to the large interindividual variability. The NCBI SNP database lists a large number of SNPs in the *CES1*, *CES2*, and *CES3* genes. In addition, several investigators reported the existence of CES SNPs [108–114]. Generally, the *CES1* gene has the most and the *CES3* has the least reported SNPs [1]. SNPs can occur in the regulatory region, intron, and exon. Some exon SNPs result in the substitutions of amino acids.

Several SNPs have been linked directly to altered pharmacokinetics of ester drugs [108–114]. For example, a patient carrying a *CES1* Gly143Glu and Asp260 frame shift shows profound defect in the hydrolytic elimination of methylphenidate, a widely used psychostimulant [109]. Even for the Gly143Glu heterozygous genotype alone, dose reduction has been recommended. SNPs in the regulatory region may have therapeutic significance as well. For example, an A to C polymorphism at –816 in the 5′-flanking region of the *CES1A1* gene shows a 30% decrease in responding to the antihypertensive agent imidapril, which requires the activation by *CES1* [113]. A reporter containing this polymorphism has significantly lower promoter activity. Like *CES1*, certain SNPs in the *CES2* gene are linked to altered clinical outcomes. For example, patients carrying the R34W heterozygous genotype have a profound alteration in the pharmacokinetics of irinotecan with a decreased AUC ratio (hydrolytic species/parent drug) by as much as 40% [111].

14.6.2 The Cytochrome P450 Enzyme System

Many drugs metabolized by CESs are also metabolized by other enzyme systems, particularly the CYP system. Hydrolysis generally proceeds faster than oxidation, therefore, hydrolysis usually determines the fate of the parent drug [85,118–121]. In some cases, hydrolysis and oxidation compete for the metabolism of a drug and the relative activity has profound clinical consequences. For example, the widely used antiplatelet agent clopidogrel undergoes both hydrolysis and oxidation [13,118–123] (Fig. 14.10). Hydrolysis represents inactivation, whereas oxidation represents activation. The hydrolysis is catalyzed by *CES1* [13], whereas the oxidation is catalyzed by several CYPs such as CYP2C19 and CYP3A4 [120–123]. Normally, 90–95% of the dosed clopidogrel undergoes hydrolysis and only ~5% of the dose is oxidized [124,125]. While extensive study has been performed on the extent of the oxidative metabolite, no report has been made on the interplay between hydrolysis and oxidation. It is expected that a slight decrease in the hydrolysis likely favors the oxidation and enhances the antiplatelet activity.

14.6.3 Uridine Diphosphate (UDP)-Glucuronosyltransferases

In addition to phase I enzymes, in many cases, the action of CESs is directly associated with the action of phase II enzymes, notably uridine diphosphate (UDP)-glucuronosyltransferases [115,126,127]. These conjugation enzymes use the cofactor uridine diphosphate-glucuronic acid (UDPG) and add sugars to lipids and other nonpolar xenobiotics. This is commonly referred to as *glucuronidation* [115]. Conjugation with a sugar moiety drastically increases the hydrophilicity thus favoring elimination. While the site of glucuronidation in a compound usually occurs at an

Figure 14.10 Hydrolysis and oxidation of clopidogrel. This antiplatelet agent undergoes both hydrolysis and oxidation. However, hydrolysis represents the major metabolic pathway (>90% of dosed clopidogrel). The P2Y₁₂ receptor belongs to a group of G protein-coupled purinergic receptors. Several CYPs have been found to catalyze the oxidation of clopidogrel, but the hydrolysis is exclusively catalyzed by CES1 [13].

electron-rich nucleophilic heteroatom such as O, N, and S, the majority of drugs for glucuronidation contain functional groups such as an alcohol/phenol or a carboxylic acid. These groups are produced by hydrolysis. In many cases, the relative activity between hydrolysis and glucuronidation has direct clinical consequences.

The hydrolysis–glucuronidation interaction is nicely illustrated by the anti-cancer prodrug irinotecan [126]. As shown in Fig. 14.11, this prodrug undergoes hydrolytic activation by CES2 to the cytotoxic metabolite SN-38, which is a potent inhibitor of DNA topoisomerase I. On the other hand, SN-38 is a substrate of UDP-glucuronosyltransferases, notably UGT1A1. Glucuronidated SN-38 no longer has therapeutic activity. As a result, an unbalanced hydrolysis over glucuronidation may increase systematic toxicity such as neutropenia. It has been demonstrated that increased SN-38 exposure is directly related to the severity of neutropenia [128]. Patients carrying the UGT1A1*28 polymorphism, particularly homozygous genotype, show a higher SN-38 AUC value and increased risk in the development of neutropenia [128].

14.6.4 Interactions with Drug Transporters

A third type of interaction as a result of the action of CESs occurs during the process of drug uptake and effluxing. Hydrolysis leads to the production of carboxylic acids, which are normally negatively charged. Charged molecules have poor membrane penetration

Figure 14.11 Hydrolysis-preceded conjugation reaction of irinotecan. This anticancer is hydrolyzed by CES2 to SN-38, which undergoes glucuronidation by uridine diphosphate-glucuronosyltransferase-1A1.

activity and are usually transported by drug transporters. Therefore, CES-coupled transporter activity is another major determinant of the efficacy and toxicity of ester drugs [129–131].

Oseltamivir, an anti-influenza viral agent, recently attracted a lot of attention from the public and scientific community because of the outbreaks of avian and swine flu. Oseltamivir, a substrate of CES1 [85], exerts potent antiviral activity through its hydrolytic metabolite. Several transporters have been shown to involve uptake or effluxing of this metabolite and parent drug as well. These transporters include multidrug resistance protein-4 (MRP4), peptide transporter-1, organic anion transporters, and P-glycoprotein [129–131]. MRP4 is localized to the basolateral membrane of

Figure 14.12 Hydrolysis-preceded transport of oseltamivir by multidrug resistance protein-4 (MRP4). The anti-influenza viral agent oseltamivir enters hepatocytes by passive diffusion and probably by active uptake as well. Subsequently, oseltamivir undergoes hydrolysis and the metabolite oseltamivir carboxylate is negatively charged and effluxed by MRP4.

hepatocytes and thus effluxes the metabolite into the blood (Fig. 14.12). On the other hand, overproduction of the hydrolytic metabolite is associated with cytotoxicity. Interestingly, oseltamivir is generally considered safe with only very few patients exhibiting liver toxicity. We recently tested whether increased expression of MRP4 protects against the cytotoxicity. Cells stably transfected with MRP4 or the corresponding vector were transfected again to overexpress CES1 and then exposed to oseltamivir. The cell proliferation rate was monitored for the toxicity. Vector cells showed marked decreases in cell proliferation when exposed to oseltamivir. In contrast, MRP4 cells showed little changes in the proliferation.

14.6.5 Drug–Insecticide Interactions

CESs are known to play critical roles in detoxification of several major types of organophosphorus, carbamate, and pyrethroid insecticides [30–35]. These hydrolytic enzymes detoxify organophosphates by acting as scavenging proteins. In contrast, CESs detoxify carbamates and pyrethroids by hydrolysis. Therefore, in all these cases, the metabolism of ester drugs should decrease. On the other hand, lower hydrolysis of

certain insecticides may alter the metabolism of drugs by other enzyme systems. For example, many pyrethroids are potent inducers of multiple nuclear receptors such as the pregnane X receptor (PXR). Activation of this receptor leads to the induction of many metabolizing enzymes such as CYP3A4. A recent study has demonstrated that the activation of PXR is significantly decreased in cells transfected with a CES [6]. It is therefore expected that coexposure to organophosphorus and pyrethroid insecticides likely increases the expression of genes regulated by PXR. It should be emphasized that the precise nature of the interactions between drug and insecticides remains largely unknown.

14.7 COMPARISON BETWEEN HUMAN AND ANIMAL CARBOXYLESTERASES

There are many similarities between human and animal CESs [2]. Like humans, all animal species studied express multiple forms of CESs with the highest CES activity being in the liver [60,65]. In many cases, compounds hydrolyzed by liver microsomes from animals are also hydrolyzed by human CESs [13]. On the other hand, there are notable differences, particularly in tissue distribution [60,62,63], regulation [85,94], and species-specific hydrolysis. Rodents but not humans, for example, have high levels of serum CESs [13,63]. The synthetic glucocorticoid dexamethasone exerts opposing effect on the regulation of several major rat and human CESs [85,94]. The local anesthetic procaine is hydrolyzed much faster by rat microsomes than their human counterparts [132]. These differences raise concerns regarding the relevance of animal models to human situation.

14.7.1 Tissue Distribution

CESs are expressed in all animal species studied. Without exception, the liver contains the highest overall CES activity in all mammalian species [65]. In addition, the gastrointestinal track, lung, and kidney have high levels of CES activity as well [1,13,63]. On the other hand, there are some notable differences. For example, rodents have high levels of CESs in the testis [62,98], in contrast, human testes contain less CES activity. Another major difference in the tissue distribution is the serum CES. Rodents but not humans contain abundant serum CESs. Actually, none of the well-characterized human CESs (i.e., CES1, CES2, and CES3) have been detected by Western blots in normal serum [13,63]. However, low level of CESs is expressed in leukocytes [133]. Certain liver diseases may increase the presence of liver CESs in the blood [134]. Nevertheless, the abundant presence of serum CESs in rodents may contribute to species difference in the metabolism of ester drugs. For example, rodents are relatively resistant to liver toxicity in response to oseltamivir [135]. One explanation is that rodents hydrolyze this antiviral agent in the blood, and only intracellular hydrolysis in hepatocytes has toxicity [76].

14.7.2 Species-Specific Hydrolysis

Like the tissue distribution, CES-based hydrolysis exhibits both similarities and differences among various species. Liver microsomes from human, monkey, dog, guinea

Figure 14.13 Examples of species-specific hydrolysis. The data were compared based on the specific activities of human and rat liver microsomes. The H/R ratios represent the specific activity on the hydrolysis of a compound by human microsomes over that by rat microsomes.

pig, hamster, mouse, and rat all contain two kinetically distinct hydrolytic activities toward *para*-nitrophenylacetate with the K_m values of 25–55 and 300–800 μM , respectively [60,93]. Significantly, the relative activity between low and high K_m CESs is comparable ranging from 40% to 60% with a single exception of guinea pig [60,93]. Microsomes from guinea pig contain predominately low K_m activity (80%). In both human and rat, the low K_m CES is responsible for the hydrolysis of clopidogrel, whereas the high K_m enzyme for the hydrolysis of aspirin [13].

Although there is remarkable similarity in the hydrolysis of certain esters among various species, these are equally remarkable in terms of species differences in hydrolyzing other esters. Figure 14.13 shows some esters that are differentially hydrolyzed by human and rat liver microsomes [44]. Deltamethrin and esfenvalerate are both pyrethroid type of insecticides. Based on the specific activity, human liver microsomes are six times as efficient as rat microsomes in hydrolyzing deltamethrin. In contrast, rat liver microsomes are twice as active as rat microsomes in hydrolyzing esfenvalerate. The local anesthetic procaine is hydrolyzed seven times faster by rat microsomes than their human counterparts [132], and likewise, meperidine is hydrolyzed much faster by rat liver microsomes than their human counterparts [136]. Conversely, lorazepam-3-acetate is a prodrug of lorazepam, a benzodiazepine type of anxiolytics, which is hydrolyzed by human microsomes approximately twice as fast as rat liver microsomes [137]. These findings demonstrate profound species differences in hydrolytic biotransformation of certain ester drugs.

14.7.3 Regulated Expression

Many factors have been shown to regulate the expression of CESs, including age, hormones, drugs, insecticides, and other chemicals [85,92–97]. Some of the factors

regulate the expression of these enzymes similarly across species. For example, the expression of CESs is very low in all species at neonatal and pediatric stage [92,97], and the anticonvulsant agent phenobarbital causes slight or moderate induction in rodents and humans [93,94]. On the other hand, some chemicals such as dexamethasone exert profound species-dependent regulatory effect. This synthetic glucocorticoid has been shown to slightly increase the expression of human CESs at micromolar concentrations [94]. In contrast, dexamethasone decreases the expression of multiple rat CESs, and significant decrease occurs even when nanomolar dexamethasone is used [85]. The decreases can be abolished by antiglucocorticoid RU486. Additionally, dexamethasone at nanomolar concentrations represses the promoters of CESs, and the repression is reduced by glucocorticoid receptor (GR)- β , a dominant negative regulator of the GR. In contrast, cotransfection of PXR increases the reporter activities, but the increase occurs only at micromolar concentrations of dexamethasone. These findings establish that both GR and PXR are involved in the regulated expression of rat CESs by dexamethasone, but their involvement depends on the concentrations [85].

In addition, structurally related compounds may have different effects on CES expression. For example, pregnenolone-16 α -carbonitrile (PCN) is structurally related to dexamethasone, and surprisingly, PCN consistently causes a moderate induction of rat hydrolase S, a secretory CES [63]. In contrast, dexamethasone suppresses the expression of this enzyme [85]. Furthermore, chemicals with the same or similar effects on the expression of CYP enzymes may differentially regulate the expression of CESs. For example, expression of rat hydrolase S is significantly suppressed by isoniazid but slightly increased by streptozotocin; both of them are CYP2E1 inducers [63,138]. The CYP1A enzyme inducers, β -naphthoflavone and 3-methylcholanthrene, have opposing effects; the former compound suppresses the expression of hydrolase S, whereas the latter compound slightly induces it [63,138]. The differential response of CES genes to the same type of CYP inducers suggests that these chemicals use multiple signaling pathways to exert their biological effects.

14.8 CONCLUSIONS/FURTHER PERSPECTIVES

CESs represent a large class of hydrolytic enzymes that are major determinants of ester/amide drugs and detoxify against organophosphorus and pyrethroid insecticides. In the past decade, tremendous progress has been made regarding substrate specificity and 3-D structure. Some progress has also been made on the regulated expression of these enzymes. Several important issues, on the other hand, remain to be established. First, increasing number of CES SNPs is identified, but it remains to be established how and to which extent these SNPs alter hydrolytic metabolism. Second, for many drugs, hydrolytic action is coupled with oxidation, conjugation, and active transportation; but the precise nature of the interactions among various systems remains to be determined. Third, it has long been postulated that CESs have a physiological role in lipid catabolism, but details on such a role are largely unknown. Finally, many drugs and disease status are shown to alter the expression of CESs, but the molecular mechanisms remain to be elucidated. In particular, how the expression of CESs is altered by the interplay between drugs and disease conditions.

15.1 SUMMARY

Phase II conjugation by the UDP-glucuronosyltransferase (UGT) family of enzymes is an important metabolic pathway for both xenobiotics and endogenous compounds. This chapter attempts to catalog the vast depth of information surrounding UGTs, including pharmacogenetics, *in vitro* aspects, and clinical relevance. Individual sections on UGT isoforms cover expression, regulation, and polymorphisms; substrates; inhibitors; active site characteristics; and clinical relevance.

15.2 INTRODUCTION

Likely due to the observation that cytochrome P450 (CYP) was involved in the metabolism of the majority of drugs, most or all drug discovery organizations screen

for oxidative clearance in human liver microsomes (HLMs) [1]. The goal of this activity is to identify early the chemical space that results in high oxidative clearance, and thus attempt to “design out” this liability. Analysis of the reasons for drug development failures over the years suggests these activities have helped reduce drug attrition due to poor human pharmacokinetics [2]. This strategy, however, increased the frequency of involvement of non-CYP-mediated enzymes in clearance pathways for new chemical entities, and these are clearance mechanisms with which we have less experience [3,4]. It stands to reason that a better understanding of, and more experience with, these metabolic pathways (e.g., glucuronidation), the enzymes catalyzing them, and the *in vitro* systems in which we can model these processes will serve to keep drug attrition due to pharmacokinetics to a minimum.

Published in 2004, a systematic review of the top 200 drugs showed that glucuronidation was the second most common biotransformation pathway, being involved in the clearance of just <10% of drugs cleared by metabolism [5]. Glucuronidation, or glucuronide conjugation, is catalyzed by the UGTs. Historically, glucuronide conjugation catalyzed by the UGTs was classified by R. T. Williams as “phase II,” being a conjugation, or “synthesis,” resulting in detoxification; “phase I” was an oxidation, a reduction, a hydrolysis, or a transformation that could increase toxicity and also provide a functional handle for conjugation [6]. This terminology has been the conventional nomenclature for the better part of 40–45 years. There has since been recommendation that this terminology be phased out, and a gradual movement away from this convention has occurred [7]. It is recognized that most xenobiotics and endogenous compounds as well are functionalized with nucleophilic atoms to allow direct conjugation, in this case glucuronidation, to readily occur. Additionally, there is a growing pool of examples of metabolic products of direct conjugation reactions having become good substrates for oxidative enzymes [8,9].

Early in the twentieth century, G. J. Dutton performed some of the first *in vitro* glucuronidations and isolated the vital cofactor UDPGA (uridine diphosphate glucuronic acid) [10]. Since that early work, our understanding of this process has gradually advanced. We know the basic reaction where the substrate (aglycone) interacts with UDPGA (which is derived from UDP-glucose), resulting in the product containing glucuronic acid and the by-product UDP (Fig. 15.1). Glucuronidation can occur on any atom with sufficient nucleophilicity [11]: O-glucuronidation can occur on alcohols, phenols, or carboxylates; N-, S-, and even C-glucuronidation have also been reported [12]. The formed conjugate is usually much more water soluble than aglycone, resulting in greater elimination in excreta, both passively and through active secretion via efflux transporters such as the multidrug-related proteins (MRPs) [13]. Important to note is that unlike most oxidative biotransformations, glucuronidation is readily reversible via hydrolysis. Chemical hydrolysis can be acid or base catalyzed [14], whereas enzymatic hydrolysis may be catalyzed by the β -glucuronidase enzyme system [15]. This enzyme is discussed later.

The human UGTs are now recognized to be a superfamily of enzymes containing more than 15 members in humans. Since 1997 [16], the general isoform nomenclature has been standardized to a convention analogous to the CYP format: UGT family number (1, 2, 3, etc.), subfamily letter (A, B, C, etc.), and member number (1, 2, 3, etc.). The xenobiotic-metabolizing isoforms are thought to reside almost completely in the UGT1A and 2B subfamilies. These UGT isoforms show significant tissue-specific expression (Table 15.1), with most forms being expressed in the liver and/or intestine.

Figure 15.1 The UDP-glucuronosyltransferase reaction mechanism.

TABLE 15.1 Sites of Expression and Probe Substrates for Select UGT Isoforms

UGT Isoform	Major Sites of Expression	Probe Substrates	References
UGT1A1	Liver, intestine	Bilirubin	19
		Estradiol	19
		Ethinylestradiol	20
UGT1A3	Liver	F ₆ -1 α ,23S,25-trihydroxyvitamin-D ₃	21
		Lithocholic acid	22
		Fulvestrant	23
UGT1A4	Liver, stomach	Trifluoperazine	24
		Imipramine	25
UGT1A6	Liver, brain	Serotonin	26
UGT1A7	Esophagus, stomach	Benzo[α]pyrene metabolites	27
UGT1A8	Esophagus, intestine	Benzo[α]pyrene metabolites	27
		Dihydrotestosterone diglucuronide	28
UGT1A9	Kidneys, liver	Propofol	20
		Entacapone	29
UGT1A10	Kidneys, intestine, lungs	Dopamine	30
UGT2B4	Liver	Hyodeoxycholic acid (6 α -OH-gluc)	31
UGT2B7	Liver, intestine, kidneys	AZT	32
		Morphine	32
		Codeine	32
UGT2B10	Liver, prostate, breast	Nicotine	33
UGT2B15	Liver, prostate	(S)-Oxazepam	34
UGT2B17	Liver, prostate	Dihydrotestosterone	35

Interestingly, some forms show significant expression in extrahepatic tissues, such as UGT1A8 and UGT1A10 in the intestine and UGT2B17 in prostate [17,18]. Most isoforms are expressed in multiple tissues, as seen in Table 15.1, such as UGT1A9 in liver and kidney and UGT1A1 in liver and intestine.

The UGTs are membrane-bound enzymes, with the majority of the protein existing in the lumen of the endoplasmic reticulum, along with a membrane-spanning region and a short cytoplasmic tail [36,37]. The enzymes consist of two regions: an N-terminal and a C-terminal domain. The C-terminal domain is highly conserved across family members and has been demonstrated to be involved in cofactor binding [38]. The N-terminal region is much more variable and is involved in aglycone acceptor specificity. Recently, a crystal structure of the C-terminal portion of UGT2B7 was published [39], and this has yielded information about amino acids involved in cofactor binding and, along with site-directed mutagenesis experiments, residues likely involved in proton transfer and catalysis (histidines and aspartates) [38]. The mechanism of UGT-mediated glucuronidation has been the subject of a significant amount of research [40,41].

An advanced understanding of the UGTs has lagged behind the CYPs, and there are a few reasons for this: the more recent commercial availability of recombinant UGT isoforms, the lack of a complete and well-characterized battery of selective probe substrates and inhibitors, and the lack of a spectrally sensitive prosthetic group such as the heme in P450s. There are many aspects of the UGTs that are very similar to the CYPs, and parallels can be made between the two systems. However, there are many differences that have been and still are being elucidated regarding experimental approaches, biochemistry, enzymology, and *in vivo* predictions. We feel that the most important aspect to accelerating our understanding of the UGTs is to organize and catalog our knowledge to date in order to build on it. This chapter serves as one of the many steps that has and will occur toward this end. The rest of this work attempts to summarize our knowledge to date regarding UGT pharmacogenetics, *in vitro* phenomena, analytical tools, and finally, individual UGT isoforms. The section for each isoform is broken down, when appropriate, by expression, regulation, and polymorphisms; substrates; inhibitors; active site characterization; and clinical relevance.

15.3 UGT PHARMACOGENETICS

The effects of pharmacogenetic variability on drug profiles and disease states are well documented. While much of the initial work focused on the genetic polymorphisms of the CYP family of drug-metabolizing enzymes, the importance of UGT polymorphisms has gained increased attention in recent years. UGT polymorphisms have been shown to be directly related to pharmacological outcomes as well as adverse drug reactions and predisposition to cancer and other diseases [42,43]. Examples include irinotecan toxicity, Crigler–Najjar and Gilbert’s syndromes, and fluctuations in breast density (a potential biomarker of one’s potential of developing breast cancer) in pre- and postmenopausal women [42,44–47].

The UGT2B subfamily is made up of at least five human isoforms, and the UGT1A subfamily contains at least eight members. Gene transcription of each gene is controlled by unique regulatory elements, as described below for each isoform. Interestingly, the manner in which the genetic structure results in gene multiplicity is very different for the two subfamilies [48]. A distinct set of exons with a unique regulatory region exists

almost exclusively for each of the UGT2B members. The multiplicity of the UGT1A family arises via a very different mechanism: alternative splicing and exon sharing. The entire UGT1A subfamily contains a shared set of exons (exons 2–5) that make up the conserved C-terminal portion of the isoform. Distinct genes arise via alternative splicing of a unique exon 1 (exon 1a1, 1a3, 1a4, etc.) to the start of exon 2. Thus, each member contains a unique N-terminus and a common C-terminus. Recently, a new exon was identified in the common region of the UGT1A locus, between the coding exons 4 and 5 [49]. This new exon can either be a terminal exon or be spliced with the common exon 5. This newly discovered splicing event leads to the production of several new mRNAs and new human UGT proteins, resulting in the production of a complicated set of enzymes of widely varying activities (some inactive). While the implications of this discovery are still being evaluated, recent coexpression data from a variety of sources (see below) suggest that considerable protein–protein interactions occur, both as homo- and heterodimerization, and that these oligomers have significant implications on enzyme activity. Genetic polymorphisms have also been shown to influence the activity of each expressed isoform, and this is discussed later in detail in each isoform's section, as appropriate (Table 15.2).

The widely varied expression levels and catalytic functions of UGT enzymes across individuals and populations have been attributed to both coding region polymorphisms as well as polymorphisms in the regulatory elements of UGTs and their respective transcription factors [101]. Well-studied examples include coding region mutations in exons 1–5 of UGT1A1 leading to Crigler–Najjar syndrome (inactive UGT1A1), TATA-promoter element mutations resulting in Gilbert's syndrome (TA insert leading to a decreased production of active UGT1A1), and polymorphisms of hepatocyte nuclear factor 1 α (HNF-1 α) and caudal-related homeodomain protein (Cdx-2) that lead to altered expression of multiple UGT isoforms [47,101–103]. In addition, epigenetics, copy-number variations, and alternative splicing mechanisms have been implicated in leading to variations in UGT phenotype profiles [48]. More specific examples of the significance of pharmacogenetics for each UGT isoform can be found in the sections below.

Concurrent with the increased focus on UGT polymorphisms has been the development of tools to study their occurrence and impact [104]. Mammalian cell lines such as COS and human embryonic kidney (HEK) 293 cells are now routinely used to express variant UGT enzymes. Recombinantly expressed variant UGT enzyme systems are commercially available as well. Human tissue samples from both wild-type and disease models have also been utilized to study genotype–phenotype associations for various UGT polymorphisms [105,106]. More recent technologies to study UGT polymorphisms include the use of RNA interference and transgenic mouse models that encompass entire human UGT gene loci in a preclinical model [107,108].

The current UGT allele terminology used in this chapter has been obtained from the UDP-Glucuronosyltransferase Allele Nomenclature Page, accessed March 9, 2010 (http://www.pharmacogenomics.pha.ulaval.ca/sgc/ugt_alleles/).

15.4 IN VITRO TOOLS

There are multiple systems available with which to study glucuronidation [109]. Cellular systems, such as fresh or cryopreserved hepatocytes, have been used extensively

to generate glucuronides. It is important to note that without special treatment (e.g., inhibitors), all enzyme activities present (oxidative and hydrolytic as well as conjugative enzymes) in the cellular system will be able to act on the substrate being incubated, which can make it rather difficult to specifically study glucuronidation in this system for drugs possessing multiple metabolic pathways. The overall result, however, is likely more physiologically relevant (see below). Tissue preparations (e.g., liver microsomes or S9) are probably the most commonly used sources of UGT activity. However, special treatment, such the use of detergents or the pore-forming peptide alamethicin, is often used to unmask the maximum activity. An advantage to liver microsomes, however, is that oxidative or conjugative processes can be studied independently, simply by the use of the appropriate cofactor (NADPH alone, UDPGA alone, or a combination of both) [110]. Recombinant UGTs have become available over the last several years, and these can be a way to study the interaction of a single isoform with a single substrate. Nevertheless, the tools exist to begin attempts at reaction phenotyping: enzyme kinetics in these various systems and inhibition with inhibitors selective for a single isoform [111]. It bears mentioning that similar to the CYPs, another enzyme system with known promiscuity in substrate processing, the UGTs frequently show atypical or non-Michaelis-Menten kinetics [17,112]. This is just one phenomenon that can add complexity to reaction phenotyping.

Activation of UGT activity is an observation that has resulted in much research. It was noted that perturbation of the membrane caused an increase in enzyme activity by an unknown mechanism [113]. Agents such as detergents or *N*-acetylglucosamine have been shown to enhance enzyme activity. The exact mechanism of enzyme activation has been unclear for some time, although membrane disruption, activation of cofactor transporters, and generation of a conformational change in the enzyme to a more active conformation have been proposed. Indeed, the mechanism of “conformation” versus “compartmentalization” was debated as to the explanation for the latency of the native enzyme [114]. More recently, the pore-forming peptide alamethicin has gained widespread use as an activator of glucuronidation [3], lending support to the compartmentalization mechanism. Interestingly, it has also been shown that some UGT isoforms are very susceptible to detergent inhibition, making this mechanism of activation (detergent treatment) rather impractical for general use [115]. Membrane disruption to remove the barrier increases enzyme activity likely by allowing cofactors and by-products to more freely diffuse into and out of the lumen of the endoplasmic reticulum. This is especially important since the by-product, UDP, has been shown to be highly inhibitory to some isoforms. UGT1A1, in particular, appears to be exquisitely sensitive to inhibition by UDP generated during glucuronidation. This has been shown to be very important for UDP generated from other isoforms, as this could lead to some rather complex results (e.g., false positives/false negatives) [116].

15.4.1 Albumin Effect

Recent efforts to understand the tendency of HLMs to underpredict intrinsic rates of glucuronidation have identified the ability of albumin to attenuate inhibition of some UGT isoforms by long-chain fatty acids. As observed for CYP2C9, unsaturated fatty acids such as arachidonic, linoleic, and oleic acids are now known to be competitive inhibitors of various UGT isoforms, such as UGT2B7 and UGT1A9 [117,118]. As such, compounds such as lamotrigine and zidovudine that are glucuronidated by

UGT2B7 have shown a significant increase in intrinsic clearance rates when 2% bovine serum albumin was included in HLM incubations [119,120]. The increase in intrinsic clearance has been attributed to a decrease in the K_m values for each substrate. It is important to note that while bovine serum albumin and fatty-acid-free human serum albumin are able to bind unsaturated fatty acids and thus decrease their inhibition potential of UGT isoforms, crude human serum albumin cannot. This is most likely due to the fact that the fatty acid binding sites of crude human serum albumin are already saturated [117].

Regardless of the system used to study glucuronidation, the ultimate purpose is usually to predict *in vivo* glucuronidation. *In vivo* clearance can be scaled with a wide variety of success, depending on the system used. Several groups have noted a systematic underprediction, often 10-fold or greater magnitude of underprediction, when using liver microsomal preparations in order to scale-up to *in vivo* clearance [121–124]. Recent data has shown that the inclusion of albumin will greatly improve the predictability of *in vivo* clearance [117]. As previously mentioned, a mechanism for underprediction was shown to be the presence of natural but inhibitory fatty acids present in microsomal preparations and released during the incubations. These fatty acids are good ligands and are therefore inhibitory for some isoforms, and albumin acts to sequester these inhibitory factors away from the active site, which allows an increase in the affinity (K_m) and thus Cl_{int} of the process [118]. Similar effects on affinity and extrapolation accuracy have been observed when attempting to predict inhibitory drug–drug interactions [119].

Another possible factor possibly affecting extrapolation accuracy is the buffer type that affects the kinetics of glucuronidation. A change in enzyme kinetics was shown when buffer was changed from tris or phosphate to carbonate buffer, and this has been shown to greatly improve the *in vivo* prediction of clearance [122]. Interestingly, much better success has been obtained in general when scaling clearance from a hepatocyte system [124]. This now gives perspective to the affinity of ligands for the UGTs in general; the statement made in the past of these being just low affinity enzymes needs to be revisited [5] because clearly the use of a more physiologically relevant system (hepatocytes) or alteration of *in vitro* conditions (albumin) can greatly increase the observed affinity to likely improve the relevance of kinetic parameters such as K_m , IC_{50} , or clearance.

15.4.2 UGT Protein–Protein Interactions

As more examples of CYP–CYP protein–protein interactions have been observed to significantly alter their activities [125,126], it has become important to consider these phenomena with regard to the UGTs. Mounting evidence now suggests that UGTs may readily function as homo- and heterodimers with regard to glucuronide formation (Fig. 15.2). Indeed, coexpression studies, immunoprecipitation studies, and others performed to investigate oligomerizations involving UGTs and elucidate their effects have identified not only significant effects of UGT–UGT interactions but also significant UGT–CYP interactions [127]. For example, a soluble form of UGT1A9 was shown to form a hetero-oligomer with UGT1A4, and this interaction significantly altered the metabolite ratio for entacapone and scopoletin. In coexpression studies, CYP3A4 was shown to alter the kinetics and regioselectivity of UGT2B7-mediated morphine glucuronidation, while other CYP isoforms had little to no effect. Follow-up experiments

Figure 15.2 Functional characterization of UDP-glucuronosyltransferase protein–protein interactions within the endoplasmic reticulum. NST, nucleotide sugar transporter; AT_{ER} , organic anion transporters located within the endoplasmic reticulum; UDP, uridine diphosphate; UMP, uridine monophosphate; X-OH, aglycone; X-OGA, glucuronidated compound. *Source:* Reprinted from Bock, Köhle. *Biochem Pharmacol* 2009;77(9):1458–1465, with permission from Elsevier.

(coimmunoprecipitation studies, overlay assay, etc.) confirmed the specificity of this interaction. FRET (fluorescence resonance energy transfer) experiments using UGT1As tagged with either yellow or green fluorescent proteins showed that homo- and hetero-oligomers were very common occurrences between UGT proteins and that the extent of interaction varied widely among the isoforms [128]. For example, UGT1A7 appeared to homodimerize the most, and the UGT1A1/1A3 and UGT1A1/1A7 hetero-oligomer also showed a strong ability to FRET, among the isoforms tested. When assessed, coexpression had a significant effect on activity. Further work needs to be done to better understand this and classify it as a curiosity, a complexity, or a concern.

15.4.3 β -Glucuronidase

Human β -glucuronidase catalyzes the hydrolysis of glucuronide metabolites leading to what has often been referred to as *a futile cycle of glucuronidation and hydrolysis*. The enzyme has been identified in most mammalian tissues, with high levels of activity in the liver, kidney, spleen, and gastrointestinal tract [129–132]. It is normally located in lysosomal fractions within these tissues, with plasma levels of the enzyme being relatively low [133]. It should be noted that differences such as pH optimum and substrate selectivity do exist between human β -glucuronidase and *Escherichia coli* β -glucuronidase [134]. *In vitro*, the presence of β -glucuronidase in HLMs and recombinant UGT membranes has been shown to result in an underestimation of rates of glucuronidation [135–137]. As such, multiple inhibitors of β -glucuronidase have been evaluated, with the most widely used being D-saccharic acid 1,4-lactone [129,131]. Additional inhibitors include polymeric phosphates of benzesterol, diene-strol, diethystibesterol, diene-strol, and hexesterol, as well as heavy metals such as Ag^{2+} , Cu^{2+} , and Hg^{2+} [131]. The use of a β -glucuronidase inhibitor *in vitro* may be useful in obtaining kinetic parameters and intrinsic activities for UGT enzymes without introducing the competing hydrolysis pathway. However, in the case where one wishes

to extrapolate *in vitro* values to *in vivo* values, it may be most appropriate to measure the net glucuronide formation rates, taking into account the physiological relevant processes of both glucuronidation and hydrolysis [138].

15.5 ANALYSIS OF GLUCURONIDES

Special consideration must often be given to the analysis and quantitation of glucuronide metabolites. Factors such as temperature and pH stability, hydrolysis back to parent, acyl migration (for ester-linked acyl glucuronides), and varying degrees of lability toward analytical conditions such as mass spectrometer source environments should all be accounted for.

The glucuronidation of a carboxylic acid group results in the formation of an acyl glucuronide and can present a complicated scenario from both an analytical as well as a toxicological standpoint. Acyl glucuronides can undergo acyl migration, in which the acyl group relocates from the C-1 carbon to the C-2, C-3, or C-4 position of the glucuronic acid moiety [139]. Acyl migration occurs through a nucleophilic attack by an adjacent hydroxyl group on the acyl carbon, resulting in an intramolecular transesterification [140,141]. The result is β -glucuronidase-resistant glucuronides and compounds with the potential to covalently and irreversibly bind to proteins, a phenomenon commonly associated with drug toxicity (Fig. 15.3). Common drugs that form acyl glucuronides include zomepirac, diclofenac, mycophenolic acid, and ibuprofen [142–145]. Analytically, migration (to the C-2, C-3, and C-4 isomers) and hydrolysis (back to parent drug) can both result in the underestimation of the amount of glucuronide present, while the latter can also cause aglycone concentrations to be overestimated. General techniques for reducing both migration and hydrolysis include acidifying the samples (pH $\sim$ 2–4) with citric or phosphoric acid, cooling the samples on ice, and storing samples at -20°C until analysis [146,147]. Furthermore, although many mass spectrometry techniques are able to detect the presence of glucuronide metabolites, the choice of more mild conditions such as electrospray ionization (as compared to atmospheric pressure chemical ionization) can also reduce the amount of glucuronide converted back to parent [148].

The use of nuclear magnetic resonance (NMR) to study and characterize acyl glucuronides has advanced in recent years. Proton NMR and two-dimensional TOCSY (*total correlation spectroscopy*) techniques have been used to assign chemical shifts to each of the protons from the eight individual acyl migration species [149,150]. In addition, the unique coupling pattern, chemical shift, and coupling constant (doublet; $\delta \sim 4.9\text{--}6.0$ ppm; $J \sim 6\text{--}9$ Hz) of the C-1 anomeric proton have proven very useful in monitoring and estimating degradation rates for β -1-*O*-acyl glucuronides [151,152]. Though not a general rule, it has been proposed that the rate of degradation can be indicative of the inherent reactivity of the acyl glucuronide and as such, the potential to cause a toxicological response [153,154].

The formation of quaternary-ammonium-linked glucuronides is another scenario that may call for specialized sample preparation and analytical conditions. While the glucuronides of primary and secondary amines have been shown to readily undergo hydrolysis under acidic conditions, N^+ -glucuronides are relatively stable at low pH and degrade at higher pH levels (pH > 10) [155,156]. Mass spectrometric analysis of N^+ -glucuronides can be complicated by the thermolability of the compounds, and it

Figure 15.3 Reactivity and rearrangement of acyl glucuronides.

should be noted that owing to the permanent positive charge of the quaternary nitrogen, detection of these compounds occurs at a mass to charge ratio that corresponds to the M^+ ion and not the normally observed $M + H$ ion [14].

15.6 INDIVIDUAL UGT ISOFORMS

15.6.1 UGT1A1

15.6.1.1 Expression, Regulation, and Polymorphisms of UGT1A1. UGT1A1 has garnered a significant amount of attention in light of its role in the metabolism of bilirubin as well as the observed effects of its functionally relevant polymorphisms. The enzyme is primarily expressed in the liver and small intestine, though UGT1A1 mRNA has also been observed in the colon, bile ducts, bladder, and stomach [18,157].

There is evidence to support the fact that UGT1A1 exists and functions as a multimeric enzyme [158,159].

As with many of the UGT isoforms that are discussed in this chapter, UGT1A1 is inducible through the activation of various nuclear receptors. UGT1A1 expression is mediated by the pregnane X receptor (PXR), the constitutive androstane receptor (CAR), and the aryl hydrocarbon receptor (AhR), with PXR effects potentially reaching clinical significance [160–162]. Both the PXR and CAR mechanisms of UGT1A1 induction may be synergistically influenced by activation of the glucocorticoid receptor [163]. Furthermore, oncostatin M (a member of the IL (interleukin)-6 cytokine family) may also increase UGT1A1 induction via the CAR, through cross talk between CAR and the oncostatin M receptor [164]. Finally, UGT1A1 expression has been shown to be upregulated by the HNF-1 α and upstream signaling factor 1/2 (USF1/2) while being downregulated by DNA methylation in colon cancer cells [165].

A major focus of UGT1A1 research has involved the pharmacogenetics of the enzyme and the clinically relevant outcomes attributed to its various polymorphisms. To date, over 100 polymorphic alleles of UGT1A1 have been reported in the literature [99]. Much of the interest surrounding UGT1A1 polymorphisms stems from the role of UGT1A1 polymorphisms in Crigler–Najjar (type I or II) and Gilbert’s syndromes, which result in hyperbilirubinemia, and in the observed toxicity profiles following irinotecan administration. The more common Gilbert’s syndrome is the result of a TA insert in the promoter region of the enzyme (UGT1A1*28, (TA)₇(TAA)) and variations in the exon 1 sequence of UGT1A1 (UGT1A1*6, G71R; UGT1A1*27, P229Q) [42,166,167]. Multiple other polymorphisms are also associated with the Gilbert’s syndrome phenotype, although it is believed that the UGT1A1*28 polymorphism is responsible for the majority of the observed variability in UGT1A1 activity [168]. Crigler–Najjar type II is associated with an additional TA insert in the promoter region (UGT1A1*37, (TA)₈(TAA)) and also results in a significant reduction in UGT1A1 expression levels [66]. The relatively rare Crigler–Najjar type I syndrome has been attributed to multiple UGT1A1 polymorphisms including UGT1A1*2 (frameshift), UGT1A1*3 (S375F), UGT1A1*4 (Q357X), and UGT1A1*5 (Q331X), and results in an absent or inactive form of the enzyme [58,169,170]. Patients with Crigler–Najjar type I syndrome generally require liver transplant [171]. A more comprehensive list of UGT1A1 polymorphisms can be found in Table 15.2.

15.6.1.2 UGT1A1 Substrates. UGT1A1 is primarily implicated in the glucuronidation of endogenous bilirubin as well as various catechols, estrogens, and flavanoids [19]. Exogenous probe substrates for the isoform include estradiol (3-OH-glucuronidation) and 17 α -ethynylestradiol [19,20]. A significant amount of research has also focused on the role of UGT1A1 in the metabolism of the topoisomerase inhibitors irinotecan, topotecan, and etoposide, as well as SN-38, the active metabolite of irinotecan [172–175]. The ability of UGT1A1 to catalyze the formation of *S*-glucuronides has been demonstrated in HLMs with the K_{ATP}-blocking agent HMR1098 [176]. Additional substrates include acetaminophen, anthraflavic acid, 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP), buprenorphine, morphine, and naltrexone [177–181]. A list of compounds that are glucuronidated by UGT1A1 can be found in Table 15.3.

15.6.1.3 Inhibition of UGT1A1. A number of clinically relevant as well as endogenous compounds have been identified as inhibitors of UGT1A1. Sulfinpyrazone ($IC_{50} = 46 \mu M$), androsterone ($IC_{50} = 125 \mu M$), and phenylbutazone ($IC_{50} = 294 \mu M$) are all inhibitors of recombinant UGT1A1 [24]. The HIV-protease inhibitors atazanavir and indinavir are also reported to inhibit UGT1A1 activity through a linear-mixed inhibition mechanism in HLMs with K_i values of 1.9 and $47.9 \mu M$, respectively [193]. It has also been observed that ketoconazole, a potent inhibitor of CYP3A4, is also a competitive inhibitor of UGT1A1-catalyzed SN-38 glucuronidation with a K_i of $3.3 \mu M$ [194]. Finally, Williams *et al.* [181] report inhibition of UGT1A1 activity by the natural products flavone, chrysin, quercetin, nobiletin, tangeretin, and bilirubin.

15.6.1.4 Active Site Characterization. It has been suggested that the active site of UGT1A1 is capable of producing complex substrate and inhibition kinetics and may consist of multiple aglycone binding sites [181,185,195]. Indeed, multiple examples of homotropic and heterotropic activation in UGT1A1-catalyzed reactions have been reported. Within the active site of UGT1A1, a histidine residue at position 39 is believed

to be the conserved histidine acting as a catalytic base in the S_N2 glucuronidation reaction [196]. Interestingly, mutation of H39 to a proline residue retained UGT1A1 activity toward estrogen-like compounds while losing the ability to glucuronidate phenolic moieties. A conserved aspartic acid residue (D151) is believed to play an important role in UDPGA binding, and as such, any mutations to this amino acid result in an inactive enzyme. Site-directed mutagenesis studies also indicate the requirement for a phenylalanine residue at position 170, most likely due to the hydrophobicity and aromaticity of the residue [197]. Computer modeling studies aimed at elucidating the local protein structure in this region of UGT1A1 also revealed an important hydrophobic region from residues 159–177 (IVAQYLSLPTVFFLHALPC) as well as a buried helix with a center around amino acid positions 169–172 of the enzyme. In addition, the presence of multiple free thiol groups from six cysteine residues within the intracisternal domain of UGT1A1 appear to be essential for enzymatic activity, although most likely not through the formation of disulfide linkers [198]. The three cysteine residues that are located within the cytosolic tail of UGT1A1 (C509, C510, and C517) are thought to be involved in the internalization of UDPGA. Finally, recent studies indicate that D36, S38, and L41 are located within the van der Waals distance to UDPGA, while either Q84, D86, K115, and I116 or K115, I116, A174, V193, and D224 have significant interactions with bilirubin, depending on the binding orientation of the substrate [199].

15.6.1.5 Clinical Relevance. Much of the clinical relevance of UGT1A1 is centered on the functional relevance of the Crigler–Najjar and Gilbert’s syndrome phenotypes. As mentioned previously, patients diagnosed with hyperbilirubinemia due to Crigler–Najjar type I syndrome often require liver transplant, whereas those with type II or Gilbert’s syndrome can be treated with UGT1A1 inducers or may even be asymptomatic [171]. Changes in the pharmacokinetic and toxicokinetic profiles of clinically administered drugs have also been attributed to variations in UGT1A1 activity. Most notable is the glucuronidation of SN-38, the active metabolite of irinotecan, by UGT1A1. The hepatic glucuronidation rates of SN-38 have been shown to highly correlate with a patient’s UGT1A1 genotype [200–203]. As such, a decreased rate of SN-38 glucuronidation due to the UGT1A1 genotype is often associated with an increased risk of neutropenia and diarrhea in patients on irinotecan therapy. While the altered clearance of SN-38 is often attributed to UGT1A1*28, the risk of irinotecan toxicity has also been associated with UGT1A1*6 [204,205]. A number of excellent reviews on the clinical manifestations of UGT1A1 genotypes on irinotecan therapy have been published [200,201,206,207]. Finally, recent data suggests that UGT1A1 genotypes may also be involved in the risk of endometrial cancer and that the significance of UGT1A1 in determining this risk is also dependent on endogenous estrogen levels as well as soy intake [208].

15.6.2 UGT1A3

15.6.2.1 Expression, Regulation, and Polymorphisms of UGT1A3. UGT1A3 is primarily expressed in the liver, with additional sites of expression including intestinal, gastric, and biliary tissues. Small amounts of UGT1A3 mRNA have also been found in the bladder [157].

Multiple mechanisms appear to play a role in the regulation of UGT1A3. The requirement of an HNF-1 α binding element on the UGT1A3 gene for UGT1A3 activity

in vitro, coupled with an increase in enzyme activity when HEK293 kidney cells were coexpressed in the presence of HNF-1 α , implicates this pathway in the transcriptional regulation of UGT1A3 [209]. In addition to HNF-1 α , UGT1A3 is also transcriptionally regulated through a xenobiotic response element as well as AhR [210]. Induction studies in human hepatocytes have also identified the oxysterol-activated nuclear receptor liver X receptor α (LXR α) as a regulator of the UGT1A3 gene [211]. In addition, the peroxisome-proliferator-activated receptor (PPAR) and PXR are involved in the regulation of UGT1A3 [22,212]. Finally, a recent study by Erichsen *et al.* [213] demonstrates transcriptional regulation of UGT1A3 by chenodeoxycholic acid and the farnesoid X receptor (FXR), suggesting a potential feedback mechanism in cholestasis.

Over 20 UGT1A3 polymorphic alleles have been identified that may play a role in drug metabolism as well as estrogen-sensitive disease states. At least five of these alleles result in synonymous amino acid sequences [73]. UGT1A3*2 (W11R/V47A) results in nearly a fourfold increase in estrone clearance *in vitro* as compared to the wild-type enzyme [214]. UGT1A3*3 (W11R) exhibits activity similar to UGT1A3*1, while UGT1A3*4 (R45W), UGT1A3*6 (W11R/V47A/M270V), and UGT1A3*8 (A158V) displayed estrone glucuronidation capacities that were at least 10-fold less than the capacity of the wild-type enzyme [73]. UGT1A3*5 (Q6R/W11R), UGT1A3*7 (F110I), UGT1A3*9 (W11R/M208L), UGT1A3*10 (V47A), and UGT1A3*11 (W11R/V47A/M114I) all displayed clearance values that were moderately lower than the value of UGT1A3*1.

15.6.2.2 UGT1A3 Substrates. While UGT1A3 (together with UGT1A4) catalyzes the glucuronidation of many tertiary amines and aromatic heterocycles resulting in quaternary ammonium glucuronides, it can also glucuronidate flavanoids, nonsteroidal anti-inflammatory drugs (NSAIDs), statins, bile acids, estrogens, and structural analogs of vitamin D [21,213–216]. More specifically, substrates include estrone and 2-hydroxyestrone, benzo[α]pyrene metabolites, 4-aminobiphenyl, 2-aminofluorene, cyproheptadine, norbuprenorphine, 4-methylumbelliferone, scopoletin, naringenin, alizarin, and 4-nitrophenol [216,217]. Phenotyping studies have revealed that glucuronidation of fulvestrant and F $_6$ -1 α ,23S,25-trihydroxyvitamin-D $_3$ appear to be relatively selective for UGT1A3 [21,23]. A more complete list of compounds glucuronidated by expressed UGT1A3 can be found in the study by Green *et al.* [217].

15.6.2.3 Inhibition of UGT1A3. A number of compounds have been recently screened for inhibition of UGT1A3-catalyzed buprenorphine and norbuprenorphine glucuronidation [218]. Both substrates were able to inhibit the other's glucuronidation with similar IC $_{50}$ values (40–50 μ M), while norbuprenorphine was also inhibited in expressed UGT1A3 by amitriptyline and temazepam. Buprenorphine has also been reported to significantly inhibit bopiramine-O-glucuronidation by UGT1A3, while diclofenac appears to be a weak inhibitor of UGT1A3 [219,220].

15.6.2.4 Active Site Characterization. Using chimera-based approaches, Kubota *et al.* [221] have shown that isoleucine 36 and histidine 40 are crucial for conveying the substrate specificity of UGT1A3 toward tertiary amines and planar phenolic compounds. It can be assumed that H40 also plays an important role as a catalytic base in the S $_N$ 2 glucuronidation reaction by UGT1A3 [41].

15.6.2.5 Clinical Relevance. *In vivo* evidence exists that describes a potential role for UGT1A3 in the outcome of patients on statin therapy. UGT1A3*2 (W11R/V47A), an allele with a frequency of 0.125 in a Japanese population and an increased glucuronidation activity as compared to wild-type UGT1A3, has been shown to increase the lactonization of atorvastatin both *in vitro* and *in vivo* [222]. As the statin lactones are known to be cleared more rapidly than the statins themselves, an increased rate of lactonization could potentially result in failure of statin therapy as well as potential adverse events. UGT1A3 may also be involved in the promotion and regulation of various disease states. For example, breast density, a potential biomarker of breast cancer risk, has been shown to be slightly lower in women who have at least one copy of the UGT1A1(TA₇)-UGT1A3(R11/A47) haplotype [223].

15.6.3 UGT1A4

15.6.3.1 Expression, Regulation, and Polymorphisms of UGT1A4. The importance of UGT1A4 is often attributed to the isoform's ability to catalyze the formation of quaternary ammonium glucuronide metabolites. The cDNA of UGT1A4 has been cloned and characterized, and its major sites of expression include the liver and the stomach [50,224]. Additional sites of expression for UGT1A4 are the bile ducts, gastrointestinal tract, and colon, while Nakamura *et al.* report that UGT1A4 mRNA is detectable in all the aforementioned tissues as well as in lung, kidney, bladder, adrenal glands, ovaries, uterus, and testis [157,225,226]. A statistically significant decrease in UGT1A4 mRNA levels has been observed in patients in an exacerbated inflammatory state [227].

As with many of the UGT isoforms, the involvement of nuclear receptors has been reported for the regulation of UGT1A4 expression. UGT1A4 induction by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) demonstrates a role for AhR in the regulation of UGT1A4, although mutation of the promoter region of UGT1A4 containing two putative xenobiotic response elements resulted in an attenuation of the observed induction [228]. The results indicate a potential dynamic interplay between the xenobiotic response elements, AhR, and UGT1A4 promoter region polymorphisms in the regulation of UGT1A4. More recently, studies in transgenic mice have identified CAR, PXR, and PPAR- α as regulators of UGT1A4 expression [229]. Finally, involvement of the estrogen receptor and specificity protein-1 have been reported in the regulation of UGT1A4 during pregnancy [230].

UGT1A4*2 (P24T) and UGT1A4*3 (L48V) are two commonly occurring polymorphic alleles of UGT1A4. The two polymorphisms have been found in 8% and 9% of German Caucasians, respectively [231]. The occurrence of UGT1A4*3 in a Japanese population has been reported to be as high as 12.5% [74]. The effect of the UGT1A4*2 polymorphism appears to be substrate dependent, while the UGT1A4*3 protein generally leads to a decreased activity compared to the wild-type UGT1A4 [231,232]. Additional polymorphisms include UGT1A4*4 (R11W), UGT1A4*5 (43fsX22), UGT1A4*6 (59fsX6), UGT1A4*7 (L48V/R91C/L150L/P268P), and UGT1A4*8, which result in a splicing defect [74]. The combined frequency of UGT1A4*4 through UGT1A4*8 was ~2% in a Japanese population.

15.6.3.2 UGT1A4 Substrates. UGT1A4 is primarily regarded for its ability to glucuronidate primary, secondary, tertiary, and aromatic amines, although it also

conjugates androgens, steroids, and progestins [224,233,234]. Substrates include the anticonvulsant lamotrigine, the antipsychotic clozapine, and compounds such as imipramine, trifluoperazine, 4-hydroxytamoxifen, senecionine, 1-substituted imidazoles, nicotine, cotinine, and the lung carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol [232,233,235–239]. Trifluoperazine and imipramine are often considered to be selective probes for UGT1A4 activity *in vitro* [24,25].

15.6.3.3 Inhibition of UGT1A4. At relatively low concentrations, hecogenin has been characterized as a selective inhibitor of UGT1A4, with an IC_{50} of 1.5 μ M [24]. Valproic acid, lamotrigine, and androsterone have also been noted to be inhibitors of UGT1A4 activity [24,119,240].

15.6.3.4 Active Site Characterization. In contrast to most of the other UGT isoforms, UGT1A4 does not maintain the conserved histidine residue within the active site of the enzyme [221]. This may explain the preference of the isoform for glucuronidating tertiary amines, a reaction that does not require deprotonation of the aglycone by a basic amino acid residue. The mechanism of O-glucuronidation by UGT1A4 is currently unknown. The lack of the histidine residue (replaced by a proline at position 40) and the presence of a threonine residue at position 36 may convey substrate selectivity for UGT1A4 versus UGT1A3 [221]. QSAR (quantitative structure–activity relationship) modeling has identified the importance of hydrophobic regions and hydrogen bonding with higher affinity UGT1A4 substrates [241]. In addition, the active site of UGT1A4 also appears to be able to accommodate complex or atypical kinetic processes. Studies assessing the interactions of dihydrotestosterone, *trans*-androsterone, tamoxifen, and lamotrigine suggest the presence of multiple aglycone binding sites that may allow for homotropic and heterotropic atypical kinetics with UGT1A4 [242,243].

15.6.3.5 Clinical Relevance. Oral clearance values for the anticonvulsant lamotrigine are known to increase by as much as 50–90% in pregnant women [244–246]. The involvement of the estrogen receptor in the upregulation of UGT1A4 may indicate that the enzyme plays an important role in the clearance of lamotrigine *in vivo* [230]. In pediatric studies, UGT1A4 enzyme activity is believed to reach its maximum levels by 1.4 years of age [247]. Potential drug interactions involving UGT1A4 have been noted for lamotrigine and olanzapine, with the former causing a modest increase in mean plasma concentrations of olanzapine [248]. Conversely, combination treatment with atazanavir/ritonavir in healthy men resulted in a slight decrease in lamotrigine exposure, most likely caused by induction of UGT1A4 by ritonavir [249]. Effects of UGT1A4 polymorphisms in clinical trials have been varied. Interestingly, the presence of a 142T>G single nucleotide polymorphism (coding for UGT1A4*3) resulted in a decreased olanzapine exposure *in vivo* [250]. This would seemingly contradict *in vitro* studies that indicate UGT1A4*3 has a decreased glucuronidation capacity, although it is entirely possible that the effects are substrate dependent. Adding to this conclusion is the observation that intrinsic clearance values for clozapine in patients carrying the UGT1A4*3 allele were twice as high as those values observed in wild-type patients [251].

15.6.4 UGT1A5

UGT1A5, previously thought to be a nonfunctional UGT due to its lack of detectable expression, was identified in human hepatocytes, Caco-2, and HepG2 cells by Finel *et al.* in 2005 [252]. Expression of the isoform was also detected in hepatic and intestinal tissue samples, with a high degree of variability in the intestine. UGT1A5 mRNA has also been reported in the kidney, bladder, and uterus [157]. Finel *et al.* also demonstrated that UGT1A5 was inducible by rifampicin and 3-methylcholanthrene, implicating a role for PXR in the regulation of UGT1A5. Known substrates for UGT1A5 include 1-hydroxypyrene, zolarsartan, SN-38, 4-methylumbelliferone, and scopoletin; however, glucuronidation rates for the last three substrates are very low [252–254].

15.6.5 UGT1A6

15.6.5.1 Expression, Regulation, and Polymorphisms of UGT1A6. UGT1A6 is a polymorphically expressed enzyme that is found in the liver, stomach, gastrointestinal tract, kidneys, bile ducts, and brain [18]. UGT1A6 mRNA has also been detected in the bladder [157]. Interestingly, while most UGT isoforms are located in the endoplasmic reticulum, UGT1A6 (together with UGT2B7) is expressed in the nucleus of HEK293 cells, potentially implicating UGT1A6 in a protective or homeostatic role in the nucleus [255].

Regulation of UGT1A6 is complex and involves multiple pathways, which result in a high degree of interindividual variability in UGT1A6 expression and activity levels. UGT1A6 is regulated by nuclear receptors such as the AhR, CAR, PXR, nuclear factor E2-related factor 2 (Nrf2), and peroxisome PPAR- α [256–261]. HNF-1 α and 4 α are also thought to be involved in UGT1A6 regulation [262]. Additional factors that may play a role in upregulating UGT1A6 expression include oxidative stress levels, vitamin A, and phosphorylation by protein kinase C, while exposure to lipopolysaccharide has been shown to result in a significant downregulation of UGT1A6 mRNA, protein, and activity [258,263–265].

Expression of UGT1A6 is highly polymorphic with at least 20 haplotypes being identified, which code for 9 UGT1A6 variants. Polymorphisms include UGT1A6*2 (S7A/T181A/R184S), UGT1A6*3 (S7A), UGT1A6*4 (S7A/R184S), UGT1A6*5 (T181A), UGT1A6*6 (S7A/S103X/T181A/R184S), UGT1A6*7 (S7A/R90H/T181A/R184S), UGT1A6*8 (T181A/R184S), and UGT1A6*9 (R184S) [75–77, 266,267]. UGT1A6*2 has been reported to occur in ~20–30% of the Caucasian and Japanese populations, while the other alleles appear to be less common and occur with frequencies of <10% each [76,266]. Compared to wild-type UGT1A6, the *2 allele is generally thought to exhibit higher rates of glucuronidation, while the *8 allele may result in a substrate-dependent alteration of glucuronidation activity [77,266,267]. It appears that many of the UGT1A6 polymorphic alleles exist in linkage disequilibrium with each other and potentially with variants of other UGT isoforms such as UGT1A1*28 [268].

15.6.5.2 UGT1A6 Substrates. UGT1A6 is generally thought to catalyze the glucuronidation of planar phenolic compounds, although the enzyme has the ability to accommodate various other structural classes as well. Substrates

for UGT1A6 include acetaminophen, polycyclic aromatic hydrocarbons, carboxylic acids such as valproic acid, and the indole-containing compounds 5-hydroxytryptophol and serotonin, which appear to be highly selective for UGT1A6 [18,26,41,75,269,270]. UGT1A6 has also been reported to be responsible for the metabolism of the anesthetic drug propofol in the human brain [271]. Additional substrates include deferiprone, *cis*- and *trans*-resveratrol, 1-naphthol, 3,4-dihydroxybenzaldehyde, 4-methylumbelliferone, 4-nitrophenol, daphnetin, and 1-hydroxypyrene [272–278].

15.6.5.3 Inhibition of UGT1A6. A number of compounds have been characterized as inhibitors of UGT1A6, including those found in natural products and food additives. Rose bengal, phloxine, and erythrosine B, all components of chemical food dyes, were shown to inhibit UGT1A6 with IC_{50} values of 15, 40, and 50 μ M, respectively [279]. Bisphenol A, used in the manufacture of plastics and a known endocrine effector, also inhibits the glucuronidation of serotonin and 4-methylumbelliferone by UGT1A6 [280]. Finally, *in vitro* experiments have identified troglitazone as a mixed-type inhibitor of UGT1A6, with a K_i value of 20 μ M [281].

15.6.5.4 Active Site Characterization. As UGT1A6 is one of the more highly characterized UGT isoforms, a fair amount of information is available regarding the protein structure of the enzyme including assessments of the aglycone and cofactor binding sites. In regard to protein positioning and localization, D488 has been shown to be the terminal residue of the transmembrane domain of UGT1A6 (at the luminal interface) and is critical for UGT1A6 location and activity within the endoplasmic reticulum [196]. In addition, deletion of a 43-amino-acid stop-transfer sequence encompassing the C-terminal transmembrane domain and adjacent cytoplasmic tail resulted in a significantly decreased enzyme activity, most likely due to the role of the sequence in endoplasmic reticulum targeting and translocation [282]. An internal signal retention sequence at residues 140–240 is also involved in the translocation of UGT1A6 into the endoplasmic reticulum [283].

Catalytically, site-directed mutagenesis studies have implicated H38 and D150 in substrate specificity and catalysis, respectively [196]. Furthermore, H54, R52, and H485, while playing key roles in the structure and function of UGT1A6, are not essential for catalysis by UGT1A6 [284]. Conversely, H370 was found to be involved in UGT1A6 catalysis, while H361 is located in the UDPGA binding site. The structural integrity of the aglycone binding site in UGT1A6 is thought to be highly dependent on interactions of the thiol moiety of C129, with other amino acids in the active site [285]. Mutation of the cysteine residue to a valine residue resulted in complete loss of enzyme activity, although substitution with serine restored activity, indicating that the inferred amino acid interactions probably did not involve a disulfide linkage. Finally, a phenolic acid binding motif has been suggested for amino acids 76–81 (KIYPVP), which are located in the substrate-binding region of the enzyme and are similar to other motifs found in phenol-conjugating enzymes [286].

QSARs and pharmacophore modeling have provided insight into the molecular properties that confer favorable physicochemical characteristics for UGT1A6 catalysis. Analysis of para-substituted phenols revealed that smaller substituents at the para position resulted in higher K_m and V_{max} parameters [287]. A negative correlation between V_{max} and molecular volume was readily apparent. Pharmacophore modeling

suggested that the presence of an aromatic ring adjacent to the nucleophilic site of glucuronidation increased the frequency of catalysis by UGT1A6 [288].

15.6.5.5 Clinical Relevance. Genetic polymorphisms of UGT1A6 have been associated with altered pharmacokinetics and increased disease risk. A more rapid clearance of salicylic acid has been observed in female patients who were characterized as being homozygous for the UGT1A6*2 allele [289]. In addition, a more rapid rate of salicylic acid glucuronidation was suggested for healthy individuals who received 650 mg of aspirin [290]. In regard to disease treatment, the UGT1A6 genotype was associated with an altered effect of aspirin on colorectal adenoma, and functional variants of UGT1A6 have been associated with a decreased risk of colorectal adenoma recurrence, as compared to carriers with wild-type UGT1A6 [291,292]. Finally, linkage disequilibrium between UGT1A6 polymorphic alleles and UGT1A1*28 may result in simultaneous hyperbilirubinemia and hyperserotoninemia as well as a subpopulation of Gilbert's syndrome or Crigler–Najjar syndrome patients who are at greater risk for altered drug metabolism and developing malignant disease [293,294].

15.6.6 UGT1A7

15.6.6.1 Expression, Regulation, and Polymorphisms of UGT1A7. UGT1A7 is primarily an extrahepatic enzyme that plays an important role in detoxification processes and may be involved in the regulation of multiple disease states. The isoform is primarily expressed in the esophagus and gastric epithelium, though UGT1A7 mRNA has also been detected in the liver, kidneys, mouth, intestine, pancreas, ovary, spleen, and lungs [18,31,157,295,296].

UGT1A7 is regulated by HNF-1 α , though unlike other extrahepatic isoforms such as UGT1A8 and UGT1A10, there is no cooperative regulation from the caudal homeodomain transcription factor Cdx2 [295]. The enzyme has been shown to be inducible by compounds such as β -naphthoflavone, 3-methylcholanthrene, and oltipraz [297–301].

UGT1A7 has been reported to be a highly polymorphic enzyme with at least 14 alleles identified to date. The different alleles have varying activity levels, as compared to wild-type UGT1A7. UGT1A7*2 (N129K/R131K), UGT1A7*6 (E139D), and UGT1A7*7 (N129K/R131K/E139D) all retain relatively high glucuronidation activity relative to UGT1A7*1 [78,79]. In contrast, UGT1A7*3 (N129K/R131K/W208R), UGT1A7*4 (W208R), UGT1A7*5 (G115S), UGT1A7*8 (N129K/R131K/E139D/W208R), UGT1A7*9 (G115S/N129K/R131K), and UGT1A7*12 (W208R/R254X) have been shown to have a decreased capacity for glucuronidation as compared to the wild-type enzyme [78,79,81,302]. UGT1A7*10 (N129K/R131K/W208R), UGT1A7*11 (R131Q), UGT1A7*13 (N276K), and UGT1A7*14 (C141S) have not been fully characterized. UGT1A7*12 results from a functional TATA-box polymorphism and exists in linkage disequilibrium with UGT1A7*3 and UGT1A7*4. The polymorphic allele may also be associated with variants of UGT1A1 such as UGT1A1*28, resulting in a significantly decreased clearance of SN-38, an active metabolite of irinotecan [302].

15.6.6.2 UGT1A7 Substrates. The localization of UGT1A7 allows the enzyme to serve an important role in the detoxification of carcinogens, pollutants, and

xenobiotics. The enzyme exhibits a broad substrate specificity with the ability to accommodate mono- and polycyclic aromatic compounds, planar as well as nonplanar compounds and compounds with sterically bulky substituents [303]. Substrates for UGT1A7 include heterocyclic amines, benzo(α)pyrene metabolites, SN-38 (7-ethyl-10-hydroxycamptothecin; both lactone and carboxylate), bisphenol A, propofol, epicatechin, thyroxine and 1-hydroxypyrene, 17 β -estradiol [27,254,277,303–306].

15.6.6.3 Inhibition of UGT1A7. *In vitro* studies have characterized amitriptyline, canrenic acid, phenylbutazone, quinidine, and quinine as nonselective inhibitors of UGT1A7 [24]. Quinine and phenylbutazone both appeared to be noncompetitive inhibitors of UGT1A7 catalyzed 4-methylumbelliferone glucuronidation, with K_i values of 784 and 3.9 μ M, respectively.

15.6.6.4 Clinical Relevance. As UGT1A7 metabolizes many compounds with carcinogenic properties, links between the activity of UGT1A7 and various disease states have been proposed. UGT1A7 genotypes, in combination with UGT1A9, have been suggested to predict both response and toxicity in colorectal cancer patients on capecitabine and irinotecan combination therapy [307]. Similarly, low activity UGT1A7 alleles have been shown to have a reduced capacity for SN-38 glucuronidation and, as such, may play an important role in irinotecan-induced toxicities [79]. In addition, the use of both the UGT1A7 and UGT1A1 genotypes appears to be a better predictor of irinotecan toxicity than the occurrence of Gilbert's syndrome alone [308]. Other disease markers such as an increased risk of hepatocellular carcinoma in hepatitis B patients, the development and extent of liver cirrhosis and the susceptibility to polycyclic aromatic hydrocarbons induced toxicities have also been associated with UGT1A7 polymorphisms [309–312].

15.6.7 UGT1A8

15.6.7.1 Expression, Regulation, and Polymorphisms of UGT1A8. Human UGT1A8 is an extrahepatic glucuronosyltransferase that appears to be expressed strictly in the esophagus, jejunum, ileum, and colon [31,295,296,313]. A single report exists of UGT1A8 mRNA in the liver and kidney [314].

Regulation of UGT1A8 in the lower gastrointestinal tract occurs through the caudal homeodomain transcription factor, Cdx2, in tandem with HNF-1 α . Expression of UGT1A8 is upregulated in the presence of 3-methylcholanthrene and rifampicin [315].

A number of polymorphisms have been identified and characterized for UGT1A8, namely, UGT1A8*1b, UGT1A8*2, and UGT1A8*3 [83]. UGT1A8*1b encodes for a nucleotide change (765A>G) that does not result in any amino acid change (T255T). UGT1A8*2 (A173G) has similar activity to the wild-type enzyme, while UGT1A8*3 (C277Y) results in a significant reduction in the glucuronidation capacity of UGT1A8 [83,316]. The relative frequency of each allele is 0.551, 0.282, 0.145, and 0.022 for UGT1A8, UGT1A8*1b, UGT1A8*2, and UGT1A8*3, respectively. Additional polymorphic alleles that have been identified include UGT1A8*4 (A144V/A173G), UGT1A8*5 (A173G/T240A), UGT1A8*6 (S126G), UGT1A8*7 (A231T), UGT1A8*8 (S43L), and UGT1A8*9 (H53N/A173G). UGT1A8*4 exhibits an increase in the formation of mycophenolic acid relative to wild-type UGT1A8 (mainly due to a decrease

in the observed K_m value), while the remaining polymorphisms generally result in a decrease in activity [317].

15.6.7.2 UGT1A8 Substrates. UGT1A8 displays a relatively broad substrate specificity and has been shown to catalyze the glucuronidation of anthraquinones, catechol estrogens, coumarins, flavanoids, 17-hydroxyandrogens, opioids, and primary amines such as that found in 4-aminobiphenyl [313]. Similar to UGT1A7, UGT1A8 also shows significant activity toward metabolites of benzo[α]pyrene [303]. UGT1A8 is uniquely capable of catalyzing the formation of a diglucuronide metabolite of dihydrotestosterone [28]. It has also been reported that the intestinal glucuronidation of raloxifene and troglitazone may be due in part to UGT1A8 as well [189,192,318]. Additional substrates for UGT1A8 include emodin, valproic acid, tea catechins, mycophenolic acid, ciprofibrate, diflunisal, furosemide, 4-hydroxytamoxifen, and tolcapone [171,192,317,319,320].

15.6.7.3 Inhibition of UGT1A8. Few reports of UGT1A8 inhibition are available; however, the effects of emodin, propofol, and β -estradiol have been described [192,321]. Emodin inhibited the glucuronidation of troglitazone in human jejunal microsomes with an IC_{50} value of 15.6 μ M; however, the influence of UGT1A10 on this interaction must also be taken into consideration [192]. Experiments aimed at assessing the inhibitor potential of propofol and β -estradiol toward UGT1A8 resulted in weak inhibition ($\sim$ 50% at 500 μ M propofol) and enzyme activation, respectively [321].

15.6.7.4 Active Site Characterization. Examination of the amino acid residues that convey glucuronidation activity to UGT1A8 has been accomplished through site-directed mutagenesis studies and characterization of the multiple UGT1A8 variants. Substitution of a highly conserved cysteine (C277) or histidine (H53) residue results in a significant loss in UGT1A8 activity, demonstrating the importance of these two residues [317]. It has been suggested that C277 may be involved in disulfide formation that is required for UGT1A8 to achieve a certain conformation [83]. Interestingly, the fairly conservative change observed in UGT1A8*7 (A231T) also results in a large decrease in the ability of UGT1A8 to catalyze mycophenolic acid glucuronidation. From the substrate perspective, compounds that exhibit a high degree of planarity and have multiple aromatic ring systems or functional groups, which lie in the plane of the aromatic ring, appear to be efficiently metabolized by UGT1A8 [303].

15.6.8 UGT1A9

15.6.8.1 Expression, Regulation, and Polymorphisms of UGT1A9. UGT1A9 is primarily expressed in the kidneys, with significant amounts of the enzyme also found in the liver, colon, testis, and ovaries [226,322,323]. UGT1A9 is thought to be the most abundantly expressed UGT isoform in renal tissue and accounts for the extrahepatic metabolism of many xenobiotics [171].

Multiple response elements are believed to be responsible for the regulation of UGT1A9. The induction of UGT1A9 by PXR ligands such as rifampin, phenobarbital, and tetrachlorodibenzodioxin suggests a role for PXR in the increased expression of UGT1A9 [324,325]. In addition to PXR, both HNF-1 α and 4 α regulate the expression

of UGT1A9 [262,326,327]. Finally, treatment of human hepatocytes and macrophages with PPAR- α and γ activators such as rosiglitazone resulted in an increase in UGT1A9 expression, suggesting that UGT1A9 is also a target gene for these nuclear receptors [328].

A number of polymorphic alleles of UGT1A9 have been identified and characterized. UGT1A9*2 (C3Y), UGT1A9*3a and *3b (M33T), UGT1A9*4 (Y242X), and UGT1A9*5 (D256N) are fairly rare, with none of the individual alleles occurring in more than 4% of the population [79,85,231,329]. The UGT1A9*3 polymorphism has a functional effect that is substrate dependent, as demonstrated by a decreased capacity for SN-38 glucuronidation but no observed effect on flavopiridol glucuronidation [79]. UGT1A9*5 has only been identified in Asian populations and results in a decreased activity compared to the wild-type enzyme [85,329].

15.6.8.2 UGT1A9 Substrates. Typical substrates for UGT1A9 include sterically hindered phenols such as 2,6-diisopropylphenol (propofol), which is a commonly used probe substrate for the enzyme [20,330,331]. UGT1A9 also catalyzes the glucuronidation of flavanoids such as luteolin, quercetin, kaempferol, and isorhamnetin; the dihydroxycoumarin analog daphnetin; and the NSAID indomethacin [275,332,333]. A considerable amount of stereoselectivity has been observed for UGT1A9, as seen with higher glucuronidation rates for (*S*)-etodolac, (*S*)-propranolol, (*R*)-oxazepam, and (*S*)-5-(4'-hydroxyphenyl)-5-phenylhydantoin as compared to their respective enantiomers [34,334–336]. Interestingly, UGT1A9 also catalyzes the C-glucuronidation of sulfinpyrazone and phenylbutazone, relatively rare instances of glucuronidation occurring at a carbon atom [337,338]. Additional substrates for UGT1A9 include 1-hydroxypyrene, 4-hydroxytamoxifen, raloxifene, mycophenolic acid, valproic acid, and clofibric acid [171,277].

15.6.8.3 Inhibition of UGT1A9. A number of compounds have been characterized as inhibitors of UGT1A9 *in vitro*. Ketoconazole, an antifungal agent and common CYP inhibitor, has been shown to inhibit the glucuronidation of SN-38 in cDNA-expressed UGT1A9 [194]. The NSAIDs niflumic acid, diflunisal, diclofenac, and indomethacin are also potent inhibitors of UGT1A9 *in vitro*, with K_i values of 0.0275, 0.710, 53.3, and 69.9 μ M, respectively [339]. As propofol is a common substrate used for UGT1A9, it is not unexpected that structural analogs of propofol would have the potential to inhibit the enzyme, as seen with 2,5-diisopropylphenol and 2,5-dimethylphenol [340].

15.6.8.4 Active Site Characterization. Various studies have been undertaken to characterize the aglycone binding site and the overall protein structure of UGT1A9. Similar to other UGTs, UGT1A9 biological activity appears to be dependent on N-glycosylation during translation [341]. The isoform is unique within the UGT family in regard to its resistance to inactivation by detergents [115]. Truncation of UGT1A9 immediately upstream from the transmembrane helix resulted in an active and water-soluble protein and implicated the transmembrane helix in potential aglycone–protein interactions [342]. Site-directed mutagenesis studies have been used to further probe for the importance of specific amino acid residues in the UGT1A9 protein structure. While UGT1A8 and UGT1A9 share a very high amino acid similarity (93–95%), there have been observed differences in substrate selectivity and these differences may be due to Arg42 and Asn152 in UGT1A9 [343]. In addition, substitution of H37, a

conserved histidine found in most UGT isoforms, resulted in almost complete loss of O-glucuronidation activity by UGT1A9, while less of a reduction was seen for N-glucuronidation [40]. Conversely, replacing D143 with an alanine residue appeared to affect both routes of glucuronidation. The authors speculate that the conserved histidine is necessary to deprotonate an oxygen nucleophile before glucuronidation. The aspartic acid residues at D143 and D148 potentially serve to stabilize the positive charges found when nitrogen is the nucleophile or on H37 after deprotonation of an oxygen nucleophile. Interestingly, a recent study with chimeric UGTs has shown the amino acids in positions 69–132 of UGT1A9 play an important role in substrate selectivity and affinity of the enzyme for phenylbutazone and 7-hydroxy-4-(trifluoromethyl)coumarin [344]. Finally, a cysteine residue at position 183 has been shown to be necessary for UGT1A9 homodimerization, although lack of this residue was not enough to fully eliminate UGT1A9 activity [345].

15.6.8.5 Clinical Relevance. As with many other UGTs, the clinical significance of UGT1A9 may be primarily related to the functional variants of the isoform. For example, the intronic UGT1A9 polymorphism I399C > T (UGT1A9*1q) appears to result in an increased rate of glucuronidation for SN-38 [105,346]. A relationship may also exist between polymorphisms that lead to reduced UGT1A9 catalysis and the prevalence of catechol-*O*-methyltransferase inhibitor-induced asymptomatic hepatic dysfunction [347]. Finally, while clinical results vary, there are examples of the effects of UGT1A9 polymorphisms on the pharmacokinetics of mycophenolic acid as well as irinotecan-related toxicities [307,316,324,348,349].

15.6.9 UGT1A10

15.6.9.1 Expression, Regulation, and Polymorphisms of UGT1A10. Expression of UGT1A10 is mostly limited to the intestine, kidney, and lung [27,157,350–352]. Although the isoform is generally considered to be a strictly extrahepatic enzyme, reports do exist of its expression in primary human hepatocytes [315]. Unlike most UGTs, UGT1A10 has been shown to be localized in an extramicrosomal fraction rather than in the endoplasmic reticulum [353].

As with UGT1A8, UGT1A10 regulation is also a cooperative effort between the caudal homeodomain transcription factor, Cdx2, and HNF-1 α [354]. Experiments in Caco-2 cells support the hypothesis that the UGT1A10 promoter does not involve a TATA-box binding region but rather occurs through overlapping Sp1/initiator binding sites [355]. UGT1A10 appears to be inducible by both 3-methylcholanthrene and rifampicin [315]. Involvement of xenobiotic and antioxidant response elements has been reported for the regulation of UGT1A10, as observed by their induction through Nrf2 and AhR activation [356]. Finally, evidence exists for the control of UGT1A10 mRNA expression through the estrogen receptor, implying that UGT1A10 may represent a unique estrogen-regulated target gene in certain cell lines [357].

Twelve polymorphic alleles have been described for UGT1A10, and a number of the polymorphisms are the result of synonymous nucleotide substitutions and do not result in any changes in amino acid sequence of enzyme activity. UGT1A10*1b (Q42Q), UGT1A10*1c (H199H), and UGT1A10*1d (H199H/A231A) are all synonymous polymorphic substitutions [86]. Other UGT1A10 polymorphisms with either uncharacterized or unchanged enzyme activities include UGT1A10*2a (E139K),

UGT1A10*3a (T240M), UGT1A10*4a (L244I), UGT1A10*4b (A231A/L244I), UGT1A10*4c (H199H/A231A/L244I), and UGT1A10*5 (M59I) [86,87,358]. Two functionally relevant mutations, UGT1A10*6 (T202I) and UGT1A10*7 (I211T), result in a 50% decrease in enzyme activity and a nonfunctional enzyme, respectively [87,88,358].

15.6.9.2 UGT1A10 Substrates. UGT1A10, in conjunction with other extrahepatic isoforms, is known to glucuronidate anthraquinones, coumarins, various amines, estrogens flavanoids, and especially phenols with considerable steric bulk [18,88,351,359]. Dopamine has been characterized as a potentially useful *in vitro* probe of UGT1A10 activity [30]. The enzyme can exhibit a stereoselective preference in regard to aglycone conjugation, as is seen with the higher rate of (*R*)-propranolol glucuronidation than that of the (*S*)-enantiomer [360]. Additional substrates include mycophenolic acid, raloxifene, menediol, the hallucinogenic indole alkaloid psilocin, and the tobacco-specific nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol [361–365].

15.6.9.3 Inhibition of UGT1A10. Tacrolimus has been found to be an inhibitor of UGT1A10-catalyzed mycophenolic acid glucuronidation *in vitro* [365]. The reported K_i value for tacrolimus in kidney liver microsomes was 27.3 ng/mL. Both 6-hydroxywarfarin and 7-hydroxywarfarin were shown to be competitive inhibitors of UGT1A10; however, this was dependent on the UGT1A10 haplotype [366]. A series of bidentate inhibitors containing both a uridine and lipophilic moiety also demonstrated moderate inhibition of UGT1A10 [367].

15.6.9.4 Active Site Characterization. Site-directed mutagenesis studies, homology modeling, and assessment of the polymorphic UGT1A10 haplotypes have allowed for a thorough characterization of the amino acid structure necessary for UGT1A10 activity. Threonine 202 and isoleucine 211 have been determined to be essential for UGT1A10 to catalyze glucuronidation reactions, while the amino acids at positions 90–93 (phenylalanine-methionine-valine-phenylalanine) play an important role in substrate recognition [30,87,88,366,368]. It has been suggested that the neutral phenylalanine residues may orient substrate molecules through hydrophobic π -stacking interactions. However, overall UGT1A10 substrate selectivity is most likely conferred by interactions among multiple amino acid residues rather than one or two individual residues [369]. Regarding the binding of UDPGA by UGT1A10, an aspartic acid residue (D393) is thought to be critical in binding the cofactor [370]. Replacement of D393 with an alanine residue resulted in complete loss of UGT1A10 activity. Lysine residues at positions 314 and 404 of UGT1A10 are also required for UDPGA binding and have been shown to be conserved across most UGT isoforms [371].

15.6.9.5 Clinical Relevance. The UGT1A10*2a polymorphism (E139K) has been associated with a significant decrease in orolaryngeal carcinoma risk [86]. Elahi *et al.* suggest that the decrease in carcinoma risk may be related to an increase in the ability of the UGT1A10*2a polymorphism to glucuronidate and thus detoxify carcinogens such as benzo[α]pyrene-7,8-dihydrodiol; however, though it is possible that the polymorphism may be linked to other polymorphisms in the UGT1A locus. Alterations in UGT1A10 expression and activity may also be related to the risk of breast cancer [372].

15.6.10 UGT2A1, UGT2A2, and UGT2A3

UGT2A1 and UGT2A2 are primarily expressed in adult and fetal nasal mucosa, while UGT2A3 expression is highest in adult hepatic and intestinal tissues [90,373]. Relatively small amounts of UGT2A2 mRNA have been reported in the lung and small intestine. Broad and overlapping substrate specificities are observed with UGT2A1 and UGT2A2 [374,375]. Interestingly, UGT2A3 maintains a highly conserved substrate specificity [90]. Substrates for UGT2A1 and UGT2A2 include 4-methylumbelliferone; 4-nitrophenol; 2-, 3-, and 4-phenylphenol; scopoletin; 1-hydroxypyrene; and estriol [373]. UGT2A3 appears to specifically glucuronidate bile acids such as hyodeoxycholic acid and is inducible through the activation of PXR [90]. Observed polymorphisms include UGT2A1 (D85Y), UGT2A1 (G308R), UGT2A1 (V391I), and UGT2A3 (T497A) [89,90].

15.6.11 UGT2B4

15.6.11.1 Expression, Regulation, and Polymorphisms of UGT2B4. UGT2B4 is an ~52-kDa protein that is primarily involved in the glucuronidation of endogenous bile acids. Although mainly expressed in the liver, UGT2B4 mRNA expression has also been detected in adipose tissue, adrenal glands, intestine, kidney, lung, mammary glands, placenta, prostate, skin, and testis [225,376]. Localization of UGT2B4 also appears to correlate with tissues commonly targeted by endogenous steroids and, as such, may play an important role in the regulation of certain cancer types [377].

As with other members of the UGT2B family, expression of UGT2B4 is linked to nuclear receptor response elements. UGT2B4 has been shown to be inducible through activation of the PPAR- α as demonstrated by the increase in UGT2B4 activity and mRNA levels in the presence of fenofibric acid or Wy 14643, both synthetic PPAR- α agonists [378]. In a similar fashion, increases in UGT2B4 mRNA, protein, and activity have been observed on activation of FXR in hepatocytes or HepG2 cell lines [379]. Interestingly, induction of UGT2B4 may serve as a negative feedback signal in the control of bile acid toxicity by decreasing the susceptibility of FXR to activation.

Significant interindividual differences have been noted for the hepatic expression of UGT2B4 [227]. The polymorphisms that have been identified for the isoform include UGT2B4*2 (D458E) and UGT2B4*3 (F109L/F369L) [94,376,377,380]. UGT2B4*2 demonstrates a similar tissue expression profile to UGT2B4 and appears to have comparable specificity and activity characteristics as the wild-type enzyme. While UGT2B4*2 is a rare polymorphism in Asian populations, a frequency of ~0.25 has been reported in a Caucasian subgroup [377]. UGT2B4*3 differs from the wild-type UGT2B4 and UGT2B4*2 in its lack of hyodeoxycholic acid activity; however, the polymorphism appears to be relatively rare [94].

15.6.11.2 UGT2B4 Substrates. UGT2B4 predominantly catalyzes the glucuronidation of bile acids, catecholestrogens such as 17-epiestriol and 4-hydroxyestrone, reduced androgens, C19-steroids, and compounds containing phenol or monoterpenoid functional groups [224,376,381–383]. The glucuronidation of hyodeoxycholic acid at the 6 α -hydroxyl group is often used as a probe for UGT2B4 activity *in vitro* due in part to its relative selectivity for UGT2B4 [31,225]. Xenobiotic substrates for UGT2B4 include the β -adrenoceptor blocker carvedilol and the “profen”

NSAIDs such as ibuprofen, ketoprofen, and flurbiprofen [182,215]. The NSAIDs diclofenac and naproxen also demonstrate glucuronidation catalyzed by UGT2B4, while indene-containing NSAIDs such as sulindac do not appear to be as readily metabolized by the enzyme. Modeling studies suggest two potential pharmacophores that lend themselves to glucuronidation by UGT2B4, the first being three hydrophobic regions within 2–4 Å of the nucleophile and the second describing a symmetrical formation of a hydrophobic region and hydrogen bond acceptor with the nucleophile of the aglycone [288]. The hydrogen bond acceptor and nucleophile were separated by ~10 Å in the pharmacophore model, with each being within 2–3 Å of a hydrophobic region of the molecule.

15.6.11.3 Inhibition of UGT2B4. Relatively few examples of UGT2B4 inhibitors are discussed in the current literature, with most displaying overlapping inhibition with UGT2B7. For example, diclofenac is often used as an *in vitro* inhibitor for UGT2B4, although it is not selective for the isoform [384]. Tredaptive (laropiprant) is a rare example of a drug noted to potentially cause clinically relevant inhibition of UGT2B4 (prescribing information).

15.6.11.4 Active Site Characterization. Information regarding the active site characteristics of UGT2B4 is primarily derived from site-directed mutagenesis studies. The introduction of a leucine residue in place of a phenylalanine residue at position 33 of UGT2B4 resulted in a significant decrease in the glucuronidation capacity of the enzyme toward hyodeoxycholic acid, 4-hydroxyesterone, and 17-epiestriol, while substitution of a tyrosine residue in the same position showed little change from the wild-type enzyme [385]. The previous results suggest the importance of an aromatic residue at this position and the potential for π -stacking interactions in substrate recognition and binding by UGT2B4. In addition, it has been proposed that a cysteine residue at position 511 in the UGT2B4 cofactor-binding domain may play an important role in the activity of the enzyme, but the functional relevance of this residue remains to be determined [91].

15.6.11.5 Clinical Relevance. While few drugs are predominantly metabolized by UGT2B4, the clinical relevance of the enzyme may stem more from its role in steroid and bile acid homeostasis. For example, the glucuronidation of cholestatic bile acids by UGT2B4 may play an important role in their detoxification by blocking the formation of carcinogenic quinone estrogens [385]. In addition, UGT2B4 may also be involved in the regulation of intracellular bile acid levels by preventing the harmful accumulation of the acids [379].

15.6.12 UGT2B7

15.6.12.1 Expression, Regulation, and Polymorphisms of UGT2B7. It has been estimated that approximately one-third of the most commonly prescribed drugs in the United States have clearance mechanisms catalyzed by UGT2B7 [5]. The ~56-kDa enzyme is primarily expressed in the liver, intestine, kidneys, brain, prostate, lungs, colon, and testis [224,386]. It has also been reported to be expressed in human placental tissue [387]. While UGT2B7 gene transcripts have not been detected in human fetal liver samples, the protein appears to be fully expressed by six months of age [388].

Recent evidence supports the involvement of nuclear receptors in the expression of UGT2B7. Levels of UGT2B7 mRNA were suppressed in Caco-2 cells when co-incubated with lithocholic acid, with involvement of the human farnesoid X receptor (hFXR) being suspected [389]. UGT2B7 expression also appears to be associated with the expression of HNF-1 α [390]. Protein expression may also be linked to disease state, with UGT2B7 mRNA levels significantly lower in patients with severe inflammation [227].

Multiple polymorphisms have been identified for UGT2B7, including UGT2B7*2 (H268Y) and UGT2B7*3 (A71S) [91,391–393]. The UGT2B7*2 polymorphism has been reported to be present in more than 50% of Caucasians and has been associated with larger cortical bone size and higher serum testosterone levels in young men [94,377,394]. Although less prevalent, the UGT2B7*3 polymorphism has been shown to affect the pharmacokinetics of carvedilol in a Japanese population [395].

15.6.12.2 UGT2B7 Substrates. UGT2B7 catalyzes the glucuronidation of a wide range of clinically relevant drugs and endogenous substrates (Table 15.4). The formation of glucuronides from morphine, codeine, or 3'-azido-3'-deoxythymidine (AZT) are often used as probe reactions for UGT2B7 activity [32,396,397]. Glucuronidation of 6 α -hydroxyprogesterone and 21-hydroxyprogesterone, as well as glucuronidation at the benzylic hydroxyl group of the β_1 -adrenoceptor-selective partial agonist denopamine, have also been suggested as being potentially selective for UGT2B7 [398,399]. UGT2B7 has demonstrated both acyl and N-glucuronidation capability as well, as observed with the glucuronidation of the carboxylic acid of diclofenac, at the primary amine moiety of carbamazepine and at the amide moiety of Maxipost [400–402]. In addition to multiple xenobiotics, UGT2B7 also catalyzes the glucuronidation of endogenous retinoid, mineralocorticoid, and glucocorticoid substrates [403–405]. The enzyme can display stereoselective metabolism, as is observed with the increased rate of glucuronidation for (*S*)-carvedilol, (*R*)-oxazepam, or (*R*)-flurbiprofen as compared to their respective enantiomers [34,406,407].

15.6.12.3 Inhibition of UGT2B7. A number of inhibitors of UGT2B7 activity *in vitro* have been characterized. Diclofenac, flurbiprofen, and mefenamic acid have been identified as potent inhibitors of UGT2B7 [406,430,431]. In addition, the anticancer drug tamoxifen; the tricyclic antidepressants imipramine, clomipramine, amitriptyline, and desipramine; and the benzodiazepines diazepam, lorazepam, and oxazepam have all been shown to inhibit morphine 3- and 6-O-glucuronidation in HLMs [432]. Ketoconazole has been reported to inhibit UGT2B7 through linear mixed-type inhibition, with K_i values of 118 and 108 μ M for morphine-3-glucuronidation and morphine-6-glucuronidation, respectively [433]. Fluconazole has been identified as a selective inhibitor of UGT2B7 [431]. In light of recent reports of herb–drug interactions, it is also important to note that several herbal components of Kampo medicine, a traditional Japanese alternative therapy, have been shown to be relatively potent inhibitors of UGT2B7 [434].

15.6.12.4 Active Site Characterization. Similar to other UGT isoforms, the characterization of the UGT2B7 active site has been somewhat hampered by the inability to generate soluble, full-length human UGTs that are amenable to crystallization. The N-terminal substrate binding site is thought to be capable of accommodating multiple

substrate molecules, and homology modeling with UGT2B7 has predicted that a histidine residue (H35) acts as a catalytic base to deprotonate the acceptor molecule in an acid–base type mechanism [39,179,423]. The resulting charged histidine residue is subsequently stabilized by a proximal aspartic acid residue (D151). Substituting H35 with a proline or alanine residue either abolished or greatly reduced the activity of UGT2B7, thus confirming the pivotal role of this amino acid in glucuronidation by UGT2B7 [39,435]. Finally, using 1D and NOESY (nuclear Overhauser effect spectroscopy) NMR experiments, Coffman *et al.* [436,437] have suggested that amino acid residues 84–118 of UGT2B7 comprise an opioid-binding pocket within the aglycone binding site.

More recently, the cofactor-binding domain of UGT2B7 has been crystallized, allowing for a more complete characterization of the interactions between UGTs and UDPGA [39]. For example, taking into account the human UGT sequence conservation and mapping it to the molecular surface of the C-terminal domain of UGT2B7 demonstrates that the UDPGA binding site is highly conserved across the various UGT isoforms (Fig. 15.4). For UGT2B7 specifically, W356, Q359, and E382 appear to have important interactions with the uracil base, while T373, H374, and N378 are predicted to interact with the diphosphate group of UDPGA through hydrogen bonding and charge stabilization. Finally, D398 and Q399 are thought to form hydrogen bonds with the glucuronic acid moiety of UDPGA and are essential for UGT2B7 activity [39].

15.6.12.5 Clinical Relevance. As mentioned previously, UGT2B7 plays at least a partial catalytic role in the metabolism of approximately one-third of prescribed medications in the United States. As such, a number of clinically relevant pharmacokinetic and pharmacodynamic phenomena involving UGT2B7 have been discussed in the literature. Most notably, the 6-*O*-glucuronide of morphine is pharmacologically active

and is ~30- to 50-fold more potent against the CNS μ -receptor than the parent compound [171,438–442]. A similar hypothesis has been put forth for the formation of codeine-6-glucuronide from codeine by UGT2B7, whereby the majority of the analgesic activity of codeine is attributed to the glucuronide metabolite and not the parent drug, though, this has not been shown clinically [443]. Interestingly, however, coadministration of diclofenac (an inhibitor of UGT2B7) to patients on codeine therapy resulted in no decrease in either the efficacy of the codeine treatment or the formation of codeine-6-glucuronide [444].

Multiple clinically relevant drug–drug interactions involving UGT2B7 have also been reported. For example, inhibition of UGT2B7 activity by probenecid or valproic acid resulted in a decreased clearance and increased AUC of lorazepam [171,445–447]. In addition, probenecid has been shown to decrease the *in vivo* clearance of clofibrac acid, diflunisal, and zomepirac [448–450], while therapeutically relevant concentrations of valproic acid are also known to affect the clearance of 3'-azido-3'-deoxythymidine (zidovudine) *in vivo* [428]. Finally, a decrease in the plasma AUC of zidovudine was observed in HIV patients who were coadministered rifampicin, possibly due to induction of UGT2B7.

15.6.13 UGT2B10

15.6.13.1 Expression, Regulation, and Polymorphisms of UGT2B10. UGT2B10 was originally isolated and characterized as an orphan protein with no known substrates or clinical relevance [451]. The enzyme is primarily expressed in the liver; however, there is evidence for UGT2B10 mRNA expression in the bladder as well [157,452]. Few reports exist describing the regulation of UGT2B10, though, increases in fibrosis and inflammation scores resulted in a downward (albeit statistically insignificant) trend in UGT2B10 mRNA expression [227].

The substitution of an aspartic acid residue for a tyrosine residue at codon 67 (UGT2B10*2; D67Y) is the sole polymorphism currently characterized for UGT2B10 [95]. UGT2B10*2 results in 5- and 16-fold lower levels of nicotine and cotinine glucuronidation, respectively. The polymorphism is present in ~9% of Caucasians and may also play a role in the decreased glucuronidation of nicotine by African-Americans, but this currently remains unclear [95,453].

15.6.13.2 UGT2B10 Substrates. The original substrates identified for UGT2B10 were endogenous metabolites of linoleic and arachidonic acid. Turgeon *et al.* [454] characterized the glucuronidation of 13-hydroxyoctadecadieneoic acid (13-HODE) as well as 12- and 15-hydroxyeicosatetraenoic acid (12-HETE, 15-HETE) by UGT2B10. Xenobiotic substrates include nicotine, cotinine, and several tobacco-specific nitrosamines such as 4-(methylbitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), N'-nitrososnicotine, N'-nitrosoanabasine, and N'-nitrosoanatabine [33]. More recently, a number of tricyclic antidepressants (amitriptyline, imipramine, clomipramine, and trimipramine) have been shown to be glucuronidated by UGT2B10 *in vitro* [455].

15.6.13.3 Active Site Characterization. Though characterization of the active site of UGT2B10 is limited, site-directed mutagenesis studies as well as the observation of regio- and stereospecific metabolism by UGT2B10 have provided some insight into the active site architecture. As mentioned previously, a highly conserved histidine residue

(H39 based on UGT1A1 sequence) is found in most UGT isoforms. Interestingly, UGT2B10 is one of only two known UGT isoforms (with UGT1A4) that does not maintain this conserved histidine. Instead, UGT2B10 has a leucine in place of the conserved histidine [456]. As UGT1A4 and UGT2B10 are the primary UGT isoforms catalyzing N-glucuronidation, the authors speculate that the replacement of the histidine residue may confer some preference toward this catalytic pathway. It is also noted, however, that a different histidine substitution in UGT1A4 (proline) suggests that more complex phenomena may also be involved in the preference for N-glucuronidation by these two isoforms. Finally, UGT2B10 has also been shown to be both regio- and stereospecific in regard to N-glucuronidation, as observed for the glucuronidation of the medetomidine enantiomers, dexmedetomidine and levomedetomidine [457]. UGT2B10 catalyzed the glucuronidation of dexmedetomidine ((*S*)-medetomidine) at both the N-1 and N-3 positions of the imidazole ring. Conversely, only the N-3 glucuronide of levomedetomidine ((*R*)-medetomidine) was observed for UGT2B10, albeit at markedly higher rates of formation than that observed for either dexmedetomidine glucuronide.

15.6.13.4 Clinical Relevance. The major clinical relevance of UGT2B10 is currently based on the effect of UGT2B4 polymorphism and the detoxification of tobacco-specific by-products. It has been noted that the UGT2B10 haplotype may predict rates of nicotine glucuronidation *in vivo*, although it is probably not the sole determinant [453]. In addition, it has been proposed that the presence of the UGT2B10*2 allele may result in an increased susceptibility to smoking-related cancers [458].

15.6.14 UGT2B11

UGT2B11 is a human orphan UGT that has been isolated and characterized, but currently has no known function [451,459]. The 52-kDa protein has a 91% sequence homology with UGT2B10 and is expressed in the liver, kidney, mammary glands, prostate, skin, adipose, adrenal, and lungs [157,459]. While UGT2B11 is thought to have a very limited range of substrates, it does catalyze the glucuronidation of 13-HODE as well as 12-HETE and 15-HETE [454]. Finally, UGT2B11 mRNA levels have been shown to be highly inducible by R1881 (methyltrienolone) [460].

15.6.15 UGT2B15

15.6.15.1 Expression, Regulation, and Polymorphisms of UGT2B15. UGT2B15 is primarily expressed in the liver and prostate, with UGT2B15 mRNA also being detected in the gastrointestinal tract, bladder, kidney, placenta, adipose, esophagus, mammary glands, ovaries, uterus, and testis [18,96,157]. In addition to the tissues mentioned above, UGT2B15 activity has been noted in the colon and trachea [452].

UGT2B15 expression is downregulated in the presence of androgens such as R1881; however, this effect may be androgen specific, as no changes in UGT2B15 expression were seen in LNCaP cells cultured in the presence of dihydrotestosterone [460,461]. Regulation of UGT2B15 occurs through ligand binding to the androgen receptor, with the effect being indirect and requiring *de novo* protein synthesis [460]. Levels of UGT2B15 appear relatively insensitive to the epidermal growth factor or cytokines such as IL-1 α [461,462]. Finally, characterization of UGT2B15 levels in an estrogen-receptor-positive cell line has demonstrated that the isoform is upregulated in the

presence of estrogen and structurally similar compounds such as propylpyrazoletriol and genistein [463].

Multiple polymorphisms have been identified and characterized for UGT2B15. UGT2B15*2 (D85Y) occurs in ~55% of Caucasians and 72% of Asians and results in a significant decrease in (*S*)-oxazepam activity [97,377]. Interestingly, UGT2B15*2 has been reported to have an increased glucuronidation capacity toward androgens [171]. UGT2B15*4 (K523T) is found in ~35% of Caucasians and 64–79% of Asians, but with no apparent effect on (*S*)-oxazepam glucuronidation activity [97,464]. UGT2B15*6 (T352I) is a rare allele that may actually result in increased UGT2B15 activity. UGT2B15*3 (L86S), UGT2B15*5 D85Y/K523T), and UGT2B15*7 (T352I/K523T) have been identified but are not well characterized at present.

15.6.15.2 UGT2B15 Substrates. UGT2B15 catalyzes the glucuronidation of endogenous steroids such as dihydrotestosterone and androstane-3 α ,17 β -diol [465,466]. The enzyme also shows some activity toward other androgens such as 5 α -androstane-3 α ,11 β ,17 β -triol and estrogens such as 4-hydroxyestrone [467]. Xenobiotic ligands for UGT2B15 include eugenol, nandrolone, oxazepam, phenolphthalene, 4-hydroxyphenytoin, 4-hydroxytamoxifen, 5-hydroxyrofecoxib, 8-hydroxyquinoline, and bisphenol A [280,419,467–469]. UGT2B15 has also been shown to catalyze the glucuronidation of a secondary metabolite of 4-hydroxy-3-methoxymethamphetamine (MDMA; Ecstasy), indicating that it may play a role in the overall metabolism of MDMA [470]. (*S*)-Oxazepam has been proposed to be a selective probe substrate for UGT2B15 [34]. Other compounds metabolized to a glucuronide metabolite by UGT2B15 *in vitro* include flavanol derivatives such as naringin, 7-hydroxyflavone, galangin, chrysin, anthraquinone analogs such as emodin and anthraflavic acid, and the D₁-dopamine receptor antagonist SCH23390 [467].

15.6.15.3 Inhibition of UGT2B15. Multiple drugs have been reported to be inhibitors of UGT2B15 *in vitro*. For example, high concentrations of valproic acid, which is not a substrate for UGT2B15, have been shown to inhibit glucuronidation of dihydrotestosterone, 5 α -androsterone-3 α ,17 β -diol, and 8-hydroxyquinoline [428]. In addition, diclofenac, ibuprofen, and flunitrazepam have been reported to be inhibitors of UGT2B15 activity in HLMs, as well as in recombinant UGT2B15 membranes [186,375]. Phenobarbital and phenytoin are also inhibitors of UGT2B15-catalyzed acetaminophen glucuronidation, with IC₅₀ values of 303 and 607 μ M, respectively [471]. Finally, soy extract, a popular herbal medicine consisting of phytoestrogens and isoflavones, has been identified as an inhibitor of dihydrotestosterone glucuronidation in recombinant UGT2B15 [472].

15.6.15.4 Active Site Characterization. Consistent with most other UGT isoforms, UGT2B15 maintains a conserved histidine residue that most likely acts as a catalytic base to deprotonate nucleophiles before glucuronidation [456]. While the specific active site residues that confer substrate specificity to UGT2B15 are unknown at this time, recent studies have shown that the isoform has the ability to demonstrate stereoselectivity in the glucuronidation of multiple compounds. For example, while (*S*)-oxazepam has been proposed as a selective probe for UGT2B15, no UGT2B15

activity toward (*R*)-oxazepam has been observed [34]. Similarly, the rate of *cis*-4-hydroxytamoxifen O-glucuronidation by UGT2B15 is ~20-fold higher than that of *trans*-4-hydroxytamoxifen glucuronidation [237]. Finally, UGT2B15 has the ability to glucuronidate both β -estradiol and epiestradiol; there is a clear preference for the latter [473]. While many complex factors convey both substrate specificity and stereoselectivity for a given enzyme, it is tempting to consider such data as an indirect analysis of the active site topography of UGT2B15.

15.6.15.5 Clinical Relevance. Much of the data surrounding the clinical relevance of UGT2B15 involves the effects of polymorphisms on the pharmacokinetics or pharmacodynamics of UGT2B15 substrates. For example, the UGT2B15*2 polymorphism has been shown to be a major determinant of the observed interindividual variability of lorazepam in healthy subjects [474]. Similarly, the same polymorphism is associated with a decrease in the *in vivo* clearance of oxazepam [475]. Multiple groups have also attempted to link variations in UGT2B15 activity with an increased risk of prostate cancer, although no direct link has been established [476,477].

15.6.16 UGT2B17

15.6.16.1 Expression, Regulation, and Polymorphisms of UGT2B17. UGT2B17 shares a 95% sequence homology with UGT2B15 and is expressed in the liver and prostate, as well as the colon, small intestine, stomach, kidneys, testis, uterus, placenta, mammary glands, adrenal glands, brain, and skin [157,452,465]. *In vitro*, UGT2B17 appears to be one of the more labile UGT proteins, as demonstrated by cycloheximide treatment of stably transfected HK293 cells expressing various UGT isoforms [383].

UGT2B17 regulation is modulated by endogenous androgens, epidermal growth factor, and IL-1 α . Treatment of prostate cancer cells with the synthetic androgen R1881, epidermal growth factor, or IL-1 α all resulted in the downregulation of UGT2B17 [460–462]. Neither IL-4 nor IL-6 appeared to have much effect on UGT2B17. Conversely, inhibition of UGT2B17 expression by small interfering RNA (siRNA) resulted in an increase in dihydrotestosterone levels in LNCaP cells and indicated that UGT2B17 may play a role in androgen-dependent gene expression and cellular reproduction [478]. Finally, UGT2B17 expression has been shown to be dependent on HNF-1 α activation, and interactions with a Pbx2-Prep1 heterodimer indicate that this complex may further modulate HNF-1 α regulation of UGT2B17 [479,480].

A single polymorphism, resulting in the deletion of a 150-kb portion of the UGT2B17 gene, has been identified and characterized [100,481]. The UGT2B17*2 deletion polymorphism results in the absence of UGT2B17 DNA in human DNA samples. The frequency of the deletion allele in humans is 0.27, with a slight difference between African-Americans and Caucasians (0.21 vs 0.33, respectively) [100].

15.6.16.2 UGT2B17 Substrates. Although one of the primary substrates of UGT2B17 is the androgen dihydrotestosterone, the isoform has shown the ability to glucuronidate various other classes of compounds including coumarins, anthraquinones, and flavanoids [35]. Specific examples include alizarin, eugenol, scopoletin, galangin, chrysin, borneol, and the NSAID ibuprofen. Unlike UGT2B15, UGT2B17 is able to glucuronidate C19-steroids at both the 3 α - and 17 β -hydroxyl

moieties [465]. However, UGT2B17 appears to selectively glucuronidate both β -estradiol and epiestradiol at only the 17 β -hydroxyl position [473]. Recent reports also note that UGT2B17 may play an important role in the metabolism of suberoylanilide hydroxamic acid, a histone deacetylase inhibitor prescribed in the treatment of cutaneous T-cell lymphomas [482].

15.6.16.3 Inhibition of UGT2B17. In addition to being substrates for UGT2B17, the NSAIDs diclofenac and ibuprofen have also been shown to be relatively weak inhibitors of UGT2B17 testosterone glucuronidation *in vitro* [375]. The two drugs appear to differ in their mechanism of inhibition of UGT2B17, with diclofenac inhibiting the enzyme through competitive inhibition, while ibuprofen appears to go through mixed inhibition.

15.6.16.4 Active Site Characterization. As mentioned previously, UGT2B17 shares at least 95% sequence homology with UGT2B15 [465]. The enzymes differ at amino acid 121, with UGT2B17 having a tyrosine residue in place of the serine residue found in UGT2B15 [96,465,483]. UGT2B17 maintains the conserved histidine residue found in most UGT isoforms [456]. Through the use of structure–activity relationships with chiral secondary alcohols, it has been proposed that UGT2B17 has a relatively flexible active site that still maintains the ability to confer significant stereoselectivity [484]. While UGT2B17 preferentially glucuronidated the (R)-enantiomers over their respective (S)-enantiomers with eudismic ratios as high as 256, it was also shown that the stereoselectivity was probably due to spatial arrangement in the active site of UGT2B17 and not due to vastly different binding affinities between the two enantiomers.

15.6.16.5 Clinical Relevance. UGT2B17 genotypes have displayed an increasing clinical relevance in recent years, both with respect to glucuronide-mediated clearance and an increased propensity for certain disease states. With a worldwide increased focus on antidoping efforts, it is interesting to note that measurements of testosterone to epitestosterone in healthy male volunteers were highly dependent on the presence of the UGT2B17*2 polymorphism [485]. Another measurable effect of the UGT2B17*2 polymorphism is that the absence of UGT2B17 protein results in an altered immunogenicity for the enzyme and influences its role as a human minor histocompatibility antigen [481]. It has also been proposed that the UGT2B17 genotype may play a role in determining risk factors for both lung and prostate cancers, although results vary [486–488].

15.6.17 UGT2B28

UGT2B28 is a 52-kDa protein that is expressed primarily in the liver, mammary glands, and LNCaP cells [489]. Significant mRNA expression has also been detected in the bladder [157]. Two polymorphisms have been identified for UGT2B28, both resulting in truncated forms of the protein with no glucuronidation activity. Known substrates of UGT2B28 include androsterone, testosterone, androstane-3 α ,17 β -diol, estradiol, hyodeoxycholic acid, and lithocholic acid [489].

15.6.18 UGT3A1 and UGT3A2

Characterization of UGT3A1 has demonstrated the major sites of expression to be in the liver and kidney, with lesser amounts of UGT3A1 mRNA detected in the stomach, intestine, and testes. Significant levels of UGT3A2 mRNA have been found in the kidneys and testes [490,491]. UGT3A1 appears to be a unique UGT isoform, in that it primarily utilizes *N*-acetylglucosamine as the cosubstrate in conjugation reactions. UGT3A1 may play an important role in bile acid homeostasis, and as such, ursodeoxycholic acid has been shown to be a good substrate for UGT3A1 [491]. 17α -estradiol, ethynylestradiol, and estrone are also glucuronidated by UGT3A1. The substrate specificities of UGT3A2 are under investigation.

15.6.19 UGT8A1

A single member of the UGT8 family, UGT8A1, has been cloned and characterized [492,493]. The UGT isoform plays an important role in the synthesis of glycosphingolipids, cerebrosides, essential myelin membrane components, and sulfatides [89]. The main catalytic function of UGT8A1 is to transfer the galactose moiety of UDP-galactose to ceramide in the biosynthesis of galactocerebrosides [494].

15.7 UGTs IN PRECLINICAL SPECIES

Many UGT isoforms have also been characterized in preclinical species such as mouse, rat, guinea pig, rabbit, canine, and nonhuman primates (NHPs) (Table 15.5). Considerable knowledge of human UGT structure and function can be gained from the study of preclinical UGTs due to the significant homology across species, especially for the UGT1A family [495]. While an exhaustive review of preclinical UGTs is beyond the scope of this chapter, some mention of their characterization, expression, regulation, and substrate specificities is most certainly deserved.

A total of 26 UGT genes or pseudogenes have been identified in mice, with 20 UGT genes being reported in rats [495,496]. Similar to human UGT isoforms, rodent UGTs are primarily located in the liver but also demonstrate a wide tissue distribution. Rodent UGTs also exhibit a sexually dimorphic profile, as observed with UGT1a1, UGT1a2, UGT1a10, and UGT2b1 in mice (all are female predominant) and UGT2B1 and UGT2B3 in rats (female and male predominant, respectively) [314,496,497]. Regulation of UGT isoforms in mice has been shown to be dependent on inflammatory or infectious disease states. Treatment of mice with either lipopolysaccharide or *Citrobacter rodentium* resulted in a downregulation of hepatic UGT1a1, UGT1a9, and UGT2b5 [498]. Furthermore, rat UGT1A1 has been shown to be inducible by 3-methylcholanthrene administration [499]. Finally, the functional relevance of rodent UGT isoforms has also been assessed, mainly in rats. Rat UGT1A6 and UGT1A7 have been characterized as the major contributors to acetaminophen glucuronidation in rats, while rat UGT2B1 is the primary isoform involved in the detoxification of NNAL and bisphenol A [500,501]. Rat hepatocytes and microsomes are also known to efficiently catalyze the glucuronidation of zidovudine *in vitro* [502].

Additional mechanistic studies have been carried out on UGT isoforms from guinea pigs. As noted earlier, UGTs are known to form homo- and heterodimers that can

affect both their catalytic capacities and substrate specificities. Ishii *et al.* [503] demonstrated that while guinea pig UGT2B21 primarily glucuronidates morphine at the 3-hydroxyl moiety, UGT2B22 shows only minor activity toward morphine. Interestingly, when the two isoforms were coexpressed in COS-7 cells, a significant increase in morphine-6-glucuronide formation was observed, indicating an altered substrate specificity potentially caused by UGT protein–protein interactions.

Finally, the examination of UGT isoforms in NHPs has revealed an important role in the metabolism of steroids, mineralocorticoids, glucocorticoids, androgens, oestrogens, opioids, and xenobiotics containing either a carboxylic acid or hydroxyl moiety [504–506]. UGT2B9 glucuronidates xenobiotics such as morphine, codeine, hydromorphone, (*S*)- and (*R*)-ibuprofen, fenoprofen, naproxen, and the natural products borneol and menthol [506]. NHP UGT2B20 has been shown to catalyze the glucuronidation of C19-steroids such as testosterone, dihydrotestosterone, and 5 α -androstane-3 α ,17 β -diol, as well as exogenous compounds such as scopoletin, 4-methylumbelliferone, and *p*-nitrophenol [504]. Finally, NHP UGT2B30 has the capacity to glucuronidate C18-, C19-, and C21 steroids as well as compounds such as 1-naphthol and *p*-nitrophenol [505]. The extrahepatic localization of NHP UGTs has implicated the enzymes as playing an important role in estrogen and androgen metabolism as well as in various steroid signaling pathways [507,508].

The use of humanized mouse models to study human UGT enzymes is an area of research that deserves mention. As multiple caveats exist when using isolated human UGT isoforms *in vitro*, the ability to study them in a more complete *in vivo* setting is of the utmost importance. A recent example of such a model is the expression of human UGT1A1*28 in a humanized mouse model [509]. The mice are hyperbilirubinemic and display a decreased rate of SN-38 glucuronidation, a known substrate of UGT1A1 [202]. The authors suggest that the model may be viewed as an important tool to be used toward understanding the effects of human UGT1A1 polymorphisms on drug metabolism.

15.8 CONCLUSIONS

The aim of this chapter was to present a comprehensive overview of the current information available on the UGT family of phase II conjugating enzymes. As research continues on the pharmacogenetics, functional characteristics, and clinical relevance of UGTs, our understanding of the catalytic mechanism, potential for drug interactions, and ability to predict *in vivo* outcomes involving this family of enzymes should greatly increase. Future challenges will include understanding the impact of UGT protein–protein interactions on *in vitro* and *in vivo* data; developing better homology models and, perhaps, crystal structures to study the structural aspects of UGTs; and refining our ability to use *in silico* modeling and simulation software to predict UGT-mediated clearance and drug interactions.

16.1 INTRODUCTION TO HUMAN SULFOTRANSFERASES

In the nineteenth century, one of the difficulties associated with surgery was the high postoperative mortality rate that many patients suffered (as high as 50%) most often due to infection [1,2]. Carbolic acid (phenol) was an early antiseptic that was used to reduce postoperative infections and thus reduce mortality [3]. In the late 1870s, a German chemist named Eugen Baumann was studying the elimination of carbolic acid in urine. He was able to isolate and characterize phenol sulfate from the urine of a patient who was administered carbolic acid as an antiseptic [4]. Many years later (1957), the molecule which served as a sulfate donor in this process was characterized [5]. Robbins and Lipman demonstrated that when protein fractions from liver cytosol were separated, one fraction contained the sulfate-activating system and a second fraction contained the transferring enzyme or a “phenol sulfokinase.” The identity of the sulfate donor molecule was determined from the sulfate-activating fraction. These investigators were able to isolate and identify what is now known as *3'-phosphoadenosine 5'-phosphosulfate* (PAPS), which is the physiological donor molecule or cofactor in sulfotransferase (SULT)-mediated conjugation reactions [5,6]. Since these early discoveries, from a historical perspective, the SULT field has moved forward relatively rapidly.

Today, SULTs are recognized as an important family of enzymes. They are not only involved in the metabolism of xenobiotics such as carbolic acid but also involved in important processes such as supporting placental estrogen biosynthesis, modulating estrogenic stimulation of the endometrium, and influencing the levels of receptor-active

thyroid hormone [7–17]. Thus, the SULT field has grown beyond the conjugation of xenobiotics, and it is now recognized that SULTs play an important role in biological processes as well. It should be noted that many insightful and complete reviews of SULT enzymology have preceded this chapter [18–24]. Moreover, the reader is directed to the references in this chapter to expand into additional topics according to his or her level of interest. However, for the purposes of this book, the scope of the current review focuses most directly on the topic of drug metabolism and the role that SULTs play in this area. An emphasis is placed on the practicality of studying SULTs as they apply to drug discovery and drug development. While a great deal of information is available for cytochrome P450 *in vivo*–*in vitro* correlations, *in vitro* assay conditions, selective substrates and inhibitors, and so on, this information is not always readily available for the SULT family of enzymes. In many cases, selective probe substrates or inhibitors do not exist, and in other cases, the selectivity of certain inhibitors of substrates has not been well characterized. For the drug metabolism scientist determining, for example, the contribution of a specific SULT isoform(s) to the formation of a sulfate drug metabolite, it is a difficult task; many of the expectations learned from dealing primarily with cytochrome P450 enzymology do not translate to the world of SULTs. It is the authors' intent that the following chapter reviews some topics that may help applied drug metabolism investigators to point themselves in the right direction for solving practical issues in drug discovery/development.

16.1.1 Classification and Nomenclature

There are two classes of mammalian SULTs: SULTs that are membrane bound and those that are found in the cytosol [18]. Membrane-bound SULTs are located in the Golgi apparatus, and these enzymes are involved in the sulfation of endogenous substrates such as protein and carbohydrates. Membrane SULTs do not currently appear to be involved in the sulfation of xenobiotics [25,26]. As a result, focus is directed toward cytosolic SULTs, which are capable of conjugating a variety of small molecules including both exogenous and endogenous substrates. It is only relatively recent that the nomenclature system for cytosolic SULTs has been established [27]. The members of the cytosolic family of SULTs are all assigned to the superfamily "SULT." In addition, based on the genetic sequence identity, the members of this superfamily are categorized and subcategorized. Those SULTs that share at least 45% amino acid sequence identity belong to the same family. Subfamilies are determined by at least 60% amino acid sequence identity. Thus, SULT1A is a designation for the SULT1 family (family designation uses an Arabic numeral after the superfamily name) and SULT1A also specifies the "A" subfamily. SULT1A1 is the name for isoform "1" (Arabic numeral) within the SULT1A subfamily. Gene names have the same designation as the proteins, but the gene names are listed in italics. Alleles are identified with an asterisk and an Arabic numeral directly after the subfamily isoform number (e.g., *SULT1A1*1*). SULT2B1a and SULT2B1b refer to splicing variants encoded by the same gene but with different amino acid sequences [28]. However, new nomenclature has designated these enzymes as SULT2B1_v1 and SULT2B1_v2, respectively.

This last point serves to illustrate a very real and sometimes confounding issue when dealing with the SULT literature. Much of the SULT body of literature consists of papers written before standardized nomenclature. Readers who are unfamiliar with the subject will be confronted with several names designated for the same protein,

which can lead to potential misunderstanding. Table 16.1 has been constructed to aid in the process of reading “older” literature. For example, the following paper published as recently as 2002 was titled “Phenol Sulfotransferase, ST1A3, as the Main Enzyme Catalyzing Sulfation of Troglitazone in Human Liver” [29]. The term ST1A3 is similar to SULT1A3; however, consultation with Table 16.1 will clarify that this paper is actually referring to SULT1A1.

16.1.2 Protein Structure and Function

The first reported SULT crystal structure was a mouse estrogen sulfotransferase (mSult1e1) [30,31]. Since then, three-dimensional (3D) structures have been determined for human SULTs 1A1, 1A3, 1E1, 2A1, 2B1_v1, and 2B1_v2 [22,32]. SULTs are globular proteins with a single α/β domain containing a central five-stranded parallel β -sheet [20]. Although many structural features identified from mSult1e1 are also observed in human SULTs, the mouse enzyme exists as a monomer, whereas human SULTs are generally present as homodimers [20,33]. A conserved sequence consisting of 10 amino acid residues (KXXXTVXXE; also known as the *KTVE motif*) located near the C-terminus in most human SULTs has been identified as being involved in dimerization [20,33]. Mutation of the valine residue alone (Val270Glu in SULT1A1, Val266Glu in SULT1E1, and Val260Glu in SULT2A1) is sufficient to convert the dimeric enzymes into monomers [33,34]. The monomeric mSult1e1 has Pro269-Glu270 residues in place of Thr and Val and, as anticipated, a double mutation of Pro269Thr and Glu270Val leads to dimerization of the enzyme [34].

One of the conserved motifs identified in mSult1e1 and in various human SULTs is the structural element that contributes to the binding of cofactor PAPS. This motif consists of nine amino acids corresponding to residues 45-TYPKSGTTW-53 in mSult1e1, and is named the 5'-phosphosulfate binding loop (5'-PSB-loop) because of its interaction with the 5'-phosphate group of 3'-phosphoadenosine 5'-phosphate (PAP) or PAPS [31,32]. Several amino acid residues have been determined to constitute the 3'-phosphate binding (3'-PB) site for PAP or PAPS, including the highly conserved residues Arg130, Ser138, and 257-RKG-259 [30]. Site-directed mutagenesis of Arg257 to Ala or Glu in SULT1A1 results in inactive proteins, illustrating the importance of this residue for the catalytic activity of the enzyme [35]. In addition to two binding motifs, aromatic–aromatic interaction (π -stacking) has also been observed for the adenine ring of the PAP molecule with residues Trp53 and Phe229 [36].

The catalytic mechanism for SULTs has been suggested to involve an inline S_N2 -type nucleophilic attack on the PAPS sulfonate by a suitable substrate nucleophile. One early study that helped to shed light on this process was a solved crystal structure of mSult1e1 with the vanadate ion (VO_4^{3-}) [31]. Vanadate (oxidation state +5) can readily acquire a stable 5-coordinated trigonal bipyramidal geometry, which mimics the transition state of both phosphate and sulfate ions. Indeed, Kakuta *et al.* were able to show that the vanadate anion adopted this bipyramidal geometry in the active site, with the three bonded oxygen atoms forming the trigonal plane surrounding the vanadium atom and the apical positions occupied by water on one side and by the terminal oxygen of the 5'-phosphate of PAP on the other. In addition, the overall structure of the mSult1e1-PAP-vanadate complex was shown to be virtually the same as the mSult1e1-PAP- β -estradiol complex obtained by the same investigators [30,31]. Subsequent crystal

TABLE 16.1 Naming Conventions and Properties of Human Sulfotransferases

Human SULT	Other Names	Major Expression Sites	Known Drug Substrates	Known Endogenous Substrates
SULT1A1	P-PST, P-PST-1, TS-PST, TS-PST-1, H-PST, HAST-1, ST1A3	Adult: liver, intestine, kidney, lung, platelets, brain, placenta Fetus: liver	Minoxidil, troglitazone, acetaminophen, ethinyl estradiol	β -Estradiol, T ₂ , T ₃ , T ₄
SULT1A2	P-PST-2, TS-PST-2, ST1A2, HAST4	Adult: liver, intestine	Minoxidil	Not known
SULT1A3	M-PST, TL-PST, HAST3, ST1A5	Adult: intestine, kidney, lung, platelets, brain, placenta Fetus: liver	Salbutamol, terbutaline, minoxidil, ethinyl estradiol	Dopamine, 3-methyl dopamine, norepinephrine
SULT1B1	ST1B2	Adult: liver, intestine, kidney, lung	—	T ₂ , T ₃ , T ₄
SULT1C2	ST1C2, SULT1C1, HAST5	Adult: stomach Fetus: liver, kidney	—	Not known
SULT1C4	SULT1C2, hSULT1C	Fetus: liver, kidney, lung	—	Not known
SULT1E1	EST, hEST, ST1E4	Adult: liver, intestine, lung, endometrium Fetus: liver, kidney, lung	Ethinyl estradiol, troglitazone	β -Estradiol, estrone, 24OH-cholesterol, T ₂ , T ₃ , T ₄
SULT2A1	DHEA-ST, HST, ST2A3	Adult: liver, intestine, lung, adrenal Fetus: liver, adrenal	Ethinyl estradiol, minoxidil,	DHEA, 24OH-cholesterol, T ₂ , T ₃ , T ₄
SULT2B1_v1	SULT2B1a	Adult: placenta	—	DHEA, pregnenolone
SULT2B1_v2	SULT2B1b	Adult: placenta, prostate	—	DHEA, pregnenolone, cholesterol, 24OH-cholesterol
SULT4A1	BR-STL	Adult: brain	Not known	Not known

structures obtained from human SULT1E1–PAPS complex and the ternary hSULT1E1–PAP- β -estradiol complex provided additional evidence for the catalytic mechanism of SULT [37]. His107 (of hSULT1E1) has been hypothesized to be a catalytic base and to activate the hydroxyl group of the substrate for nucleophilic attack via proton abstraction. Mutation of this residue (His107Asn) leads to an enzymatically inactive protein [37]. Once activated, the oxygen anion attacks the sulfur atom of the PAPS molecule, resulting in the dissociation of the bridging oxygen between the 5'-phosphate and the sulfate leaving group. A conserved lysine residue (Lys47) has been suggested to act as an acid catalyst by interacting with the bridging oxygen and therefore facilitating the dissociation of the sulfate group from PAP. Interestingly, in the absence of substrate, the crystal structure of PAPS-bound human SULT1E1 showed that Lys47 actually interacted with Ser137 via a side chain interaction (hydrogen bonding) and that this interaction prevented the hydrolysis of PAPS. It was proposed that once the substrate was bound in the active site, and the reaction progressed, the bridging oxygen between the 5'-phosphate and the sulfate group then attained a partial negative charge after the attack of the substrate oxyanion (Fig. 16.1). At this point, the side chain of Lys47 switched from the Ser137 interaction to the partial negative charge of the bridging oxygen, stabilizing this intermediate and thus making the phosphate a better leaving group. Taken together, the results from crystallography and site-directed mutagenesis studies have suggested a detailed structural catalytic mechanism. Although there may be refinements to this proposed mechanism, the data indicate that the conserved serine, lysine, and histidine residues work in concert during the sulfonate transfer process [37].

16.1.3 Tissue Distribution

Sulfation has been shown to be a major biotransformation pathway for a number of xenobiotics (e.g., ethinyl estradiol, salbutamol, and troglitazone) [38–41] as well as an inactivation/regulation mechanism for endogenous chemicals such as dopamine [42]. Section 16.1 briefly touched on some of the important endogenous roles for SULTs. Not surprisingly, broad expressions of SULT enzymes have been identified in various tissues as would be expected for a family of enzymes with many different roles. Major expression sites for different SULT enzymes are summarized in Table 16.1. Using quantitative immunoblotting, Riches *et al.* [43] determined the expression levels of five major SULTs (SULT1A1, SULT1A3, SULT1B1, SULT1E1, and SULT2A1) in adult liver, small intestine, kidney, and lung. The overall amount of SULT expressed in liver and intestine was greater than 10-fold of that observed in lung and kidney. In liver, SULT1A1 and SULT2A1 were determined to be the major SULT isoforms, with SULT1B1 and SULT1E1 expressing at relatively lower levels. There was no detectable level of SULT1A3 in liver. The expression pattern of various SULTs in intestine was markedly different from that in liver, with SULT1A3 and SULT1B1 more abundant than SULT1A1, SULT1E1, and SULT2A1. In a similar study conducted by Teubner *et al.* [44], high SULT expression levels were detected in ileum compared to the remaining intestinal sections (jejunum, cecum, colon, and rectum). Subsequent immunohistochemical analyses revealed that SULTs were primarily expressed in mature (differentiated) enterocytes (similar to cytochrome P450 3A), consistent with the anticipated role of xenobiotic detoxification. It is interesting to note that SULT1C2 was detected in stomach, while SULT1A2 was present at very low levels in liver and intestines. In addition, significant interindividual differences in SULT expression levels were observed in the tissues examined.

Figure 16.1 Proposed mechanism of sulfotransferase-catalyzed sulfonyl transfer.

Results obtained from reverse transcriptase-polymerase chain reaction (RT-PCR) analyses indicated that SULT1A1, SULT1A3, and SULT4A1 were readily expressed in human brain [45,46]. Immunoblot analyses showed that SULT1A1, SULT1A3, and SULT4A1 proteins were present in all regions of the brain examined; however, the expression patterns for these SULTs were vastly different [47,48]. SULT1A1 was preferentially expressed in cerebellum, occipital, and frontal lobes, whereas SULT1A3 was highly expressed in superior temporal gyrus, hippocampus, and temporal lobe. The expression level of SULT4A1 was relatively consistent among various regions tested. At the cellular level, immunoreactivities for SULTs 1A1 and 1A3 were found in neurons as well as glial cells, but localization of SULT4A1 was mainly associated with neurons. Currently, despite abundance, the role and function of SULT4A1 in human brain is undetermined.

16.1.4 Role in Fetal Development

Similar to adults, the developing fetus is potentially exposed to a number of environmental toxins; it has been hypothesized that SULTs play a protective role during development because a number of SULTs are expressed at high levels during this period [18]. However, it should be added that other xenobiotic-metabolizing enzymes are also present in the fetus, one notable example would be CYP3A7 and other P450 enzymes [49,50]. Several investigators have shown that SULT2A1 [dehydroepiandrosterone (DHEA) SULT] increases during fetal development, and the expression of SULT2A1 is very high in the adrenal from ~12 weeks of gestation onward, which lends credence to the idea that DHEA sulfate is needed during this period to support placental estrogen biosynthesis [51,52]. DHEA is sulfated primarily by SULT2A1 in the adrenal cortex and then desulfated in the placenta to release free DHEA [53]. The DHEA sulfate in placenta is from both maternal and fetal adrenal origin [54,55], and once free DHEA is released, it is then converted into androstenedione by the 3 β -hydroxysteroid dehydrogenase type 1 (3 β -HSD1), next aromatized to estrone by the cytochrome P450 aromatase and finally reduced by the 17 β -HSD type 1 to generate estradiol [56].

Thyroid hormones are critical for development of the fetal and neonatal brain, as well as for many other aspects of fetal growth (e.g., thyroxine). Hypothyroidism in either the mother or fetus often results in fetal disease; in humans, this can include a high incidence of mental retardation [57–59]. The fetal thyroid gland reaches maturity by week 11–12, close to the end of the first trimester, and begins to secrete thyroid hormones by about week 16 [60]. During this period, an adequate supply of maternal thyroid hormones must be sustained to ensure normal neurological development.

The mechanism by which thyroxine (T_4) is converted to the receptor active form 3,3',5-triiodothyronine (T_3) is a complex interplay of sulfation and deiodination between free T_4 and T_3 . When T_4 is secreted by the thyroid gland, it can be activated to form T_3 (outer ring deiodination) or inactivated to reverse T_3 (inner ring deiodination). However, when T_4 is sulfated, it is almost completely converted to receptor inactive reverse T_3 . Sulfation of T_3 also accelerates the deiodination of T_3 to T_2 (3,3'-diiodothyronine) [14,15,17,60].

It has been shown that iodothyronine sulfates are present at very high levels in fetal blood and postnatal life, and thus, it has been speculated that sulfation may play part of a protective mechanism that prevents the fetus from excessive T_3 exposure [61,62]. However, other mechanisms are also present and low fetal serum concentrations of

T₃ are due, in part, to the increased activity of the inactivating deiodinase (D₃) and a low expression of the activating deiodinase D₁ (the major activating deiodinase in adults) [63]. Although the major contributing mechanism may be subject to debate, it is interesting that the expression of deiodinase and high sulfate levels of thyroid hormones are all mechanisms that would reduce fetal exposure to T₃.

16.2 SULFATION REACTION

As discussed, since the early work of Eugen Baumann, examples of drug sulfation have grown substantially. Many review papers on this subject have wording such as “Sulfonation of the low molecular weight compounds catalyzed by members of the cytosolic SULT multigene family is an important determinant of the pharmacology and toxicology of a vast array of endogenous and foreign chemicals...” [21]. However, in the pharmaceutical industry as well as in the literature, the overall contribution of sulfation to drug metabolism is often overlooked. For example, in a recent review of cytochrome P450 and other drug-metabolizing enzymes, the author presents a pie schematic outlining the contribution of cytochrome P450s (CYPs or P450s), UDPGA-glucuronosyltransferases (UGTs), esterases, *N*-acetyltransferases (NATs), and monoamine oxidases (MAOs), but no slice of the pie was designated for the contribution from SULTs [64]. In addition, over the course of many collective years of industrial experience (and many hundreds of compounds), we have worked on relatively few drugs that undergo sulfation as the primary means of elimination. However, we have also made the observation that sulfation has grown in importance in the industrial setting in recent years. Several suggestions may be offered to rationalize this undocumented observation. First, in early drug discovery, much attention is focused on P450- and UGT-mediated metabolism. As a consequence, when discovery teams seek to minimize metabolism/clearance caused by these enzymes, the process (likely inadvertently) shifts the chemical space of compounds such that other pathways (e.g., active transport and sulfation) play an increasing role in compound elimination. Second, microsomes-based metabolic stability studies have been utilized as front-line assays for years. Given that drug-metabolizing SULTs are cytosolic, the microsomal system will not yield useful information regarding the potential sulfation of drug candidates. However, because the contemporary quality and availability of cryopreserved hepatocytes has improved, microsomal assays are increasingly complemented by *in vitro* assays using hepatocytes, which generate metabolism information from a whole cell system, and therefore include the contribution to metabolism from many enzymes including SULTs [65]. Regardless of the true reason for the increasing role of sulfation, given the potential for SULTs to conjugate a wide variety of xenobiotic compounds, it would be prudent for drug metabolism scientists (academic or industrial) to be familiar with the basics of SULT conjugation. Accordingly, this section focuses on the basic catalytic mechanism, *in vitro* assays, enzyme kinetics, practical considerations, and examples of conjugation leading to the formation of potential deleterious reactive intermediates.

16.2.1 Catalytic Mechanism

Sulfation (or sulfonation) is the transfer of a sulfonate group ($-\text{SO}_3^-$) to an acceptor molecule. A structural mechanism for this reaction was discussed in Section 16.1.2.

Figure 16.2 Example of a sulfonate conjugation reaction.

The acceptor in this reaction is commonly a hydroxyl group, in which case a sulfate is formed ($\text{RO-SO}_3\text{H}$; Fig. 16.2). It should be noted that some authors prefer to use the term “sulfonation” rather than “sulfation,” since technically it is the sulfonate group, not the sulfate group ($-\text{OSO}_3^-$), that is being transferred in the reaction. Regardless of terminology, a hydroxyl group can serve as the nucleophile/acceptor and it is also possible for nitrogen or sulfur to act as a nucleophile and form a sulfamate or thiosulfate metabolite, respectively. As discussed in Section 16.1.1, for small molecules, this reaction occurs primarily in the cytosol, catalyzed by cytosolic SULT enzymes. In general, the catalytic turnover of substrates catalyzed by SULT enzymes is relatively low. For example, the k_{cat} for sulfation of β -estradiol by SULT1E1 is $\sim 1.3/\text{s}$ [66]. However, the K_{m} values for many substrates are low (in the nanomolar range), resulting in high catalytic efficiency ($k_{\text{cat}}/K_{\text{m}}$).

Early crystallography studies were not able to determine a structure with both PAPS and an acceptor molecule bound to SULT simultaneously. Instead, structures of mouse Sult1e1 were solved as mSult1e1-PAP- β -estradiol complex and mSult1e1-PAP-vanadate complex (*vide supra*) [30,31]. Similarly, structures of human SULT1E1-PAPS and human SULT1E1-PAP- β -estradiol complexes were also obtained [37]. Insight into the mechanisms of sulfonate transfer was gained by superimposing the structures of the later two complexes, and the resulting superposition revealed a ternary complex that positioned PAPS with the acceptor substrate in a $\text{S}_{\text{N}}2$ -like inline displacement reaction [37]. In Section 16.1.2, a detailed description (hypothesis; Fig. 16.1) of this mechanism was presented. Recently, a group was able to provide a snap shot of the Michaelis–Menten complex with both PAPS and 4-nitrophenol bound to mouse Sult1d1 [67]. The data from this complex also strongly supported the $\text{S}_{\text{N}}2$ inline displacement mechanism as proposed by earlier studies.

16.2.2 Sulfation Assays

For many decades, the barium precipitation assay developed by Foldes and Meek [68] has been commonly adopted for determining SULT activities. This assay takes advantage of the highly effective precipitation process of PAPS in the presence of barium ions. With the use of $[^{35}\text{S}]$ -labeled PAPS as the cosubstrate, the unreacted $[^{35}\text{S}]$ PAPS can be easily removed from the incubation mixture by precipitation, leaving the soluble, $[^{35}\text{S}]$ -labeled sulfate conjugates readily available for quantification by scintillation counting.

However, this simple, quick, and widely applicable [^{35}S]PAPS assay does have some limitations. One major disadvantage is the inability to differentiate what exactly has been sulfated. It has been shown that contaminants of substrate and buffering agent, as well as small peptides present in tissue preparations, can undergo significant sulfation, and as a consequence, there is potential to confound experimental results [69]. The background signal caused by these undesired sulfation products are particularly problematic in determining product formation rates at low substrate concentrations. Many steroids, for example, have K_m values in the low nanomolar region. To overcome this hurdle, thin-layer chromatography (TLC) has been commonly utilized in recent years to replace barium precipitation when [^{35}S]PAPS is used [42,70,71]. The ability to separate various [^{35}S]-labeled sulfate conjugates also enables a more thorough characterization of metabolism and kinetic analysis. For compounds such as raloxifene and 24-hydroxycholesterol, TLC analyses reveal the formation of secondary metabolites (i.e., disulfates) in addition to monosulfates from *in vitro* incubations. In the case of dopamine, sulfation products of dopamine and its metabolite, 3-methyldopamine, have been identified in the incubation of dopamine with human neuroblastoma cells. The usefulness of TLC analysis, however, is limited by resolving power, as illustrated by the inability to separate isomeric monosulfate conjugates [42,70,71].

High performance liquid chromatography (HPLC)-based methods provide much needed resolution for various sulfate conjugates, including isomeric conjugates, leading to more precise measurements of SULT activities and kinetic analyses. Traditional reversed-phase column chromatography using a C18 column is broadly applicable for many endogenous substrates and xenobiotics [70–72]. For highly hydrophilic substrates such as dopamine and 3,4-dihydroxymethamphetamine, separation can now be readily achievable with a fluoro-substituted alkyl column or a hydrophilic interaction chromatography (HILIC) column [73,74]. Depending on the application, column effluent can be analyzed using one or more online detectors, including UV/VIS spectrophotometer, fluorescence spectrophotometer, radiochemical detector, and mass spectrometer. Liquid chromatography-mass spectrometry (LC/MS) appears to be the most versatile and convenient, albeit expensive, method among those listed above. Although the pK_a of the sulfate moiety is ~ 1 , a sulfate conjugate can be detected using a positive or negative ionization mode depending on the pH of the mobile phase used [73–75]. Constant neutral loss of 80 Da (sulfonate moiety) is a generic yet selective way for the detection of sulfate conjugates. It should be noted that the loss of sulfonate moiety can readily occur via in-source collision-induced dissociation (i.e., in-source fragmentation). As such, extra care should be taken to optimize the ionization condition for sulfate conjugates. The labile nature of the sulfonate moiety in mass spectrometric analysis makes the identification of the sulfation site very difficult. Additional nuclear magnetic resonance (NMR) analyses and/or preparation of synthetic standards are commonly performed in conjunction with LC/MS analyses [73,74].

16.2.3 Enzyme Kinetics and Some Practical Considerations

16.2.3.1 Kinetics. In Section 16.2.1, the catalytic mechanism of SULTs was presented. As discussed in this section, published data strongly support a ternary S_N2 inline displacement mechanism. One additional question that has been studied is the exact order of binding and the extent to which reaction products (e.g., PAP) are also

bound. In particular, understanding the binding order offers a mechanistic understanding for the phenomena of substrate inhibition (i.e., lower product formation as substrate concentration is increased). Atypical kinetics (e.g., substrate inhibition and autoactivation) displayed by drug-metabolizing enzymes such as P450s and UGTs can also be observed in SULTs [36,66,76–79]. For example, in the case of human, SULT1E1-catalyzed sulfation of β -estradiol, substrate inhibition was so prominent that it was observed even at concentrations below 100 nM [66].

Early studies by Duffel and Jacoby found that the kinetic binding mechanism of aryl SULT (purified from rat liver) was described by a random Bi Bi mechanism with two dead-end product–inhibitor complexes, which was also consistent with a study conducted by Zhang *et al.* using recombinant human SULT1E1 [66,80]. On the other hand, a sequential/ordered mechanism was proposed to describe kinetics determined in human SULT1A3 as well as SULTs obtained from rat and rhesus monkey liver [81–84]. Regardless of the exact order of binding, enzyme kinetic studies have postulated that substrate inhibition can result from noncatalytic dead-end complexes (e.g., enzyme bound to substrate and PAP).

However, formation of dead-end complexes is not the only hypothesis that can rationalize substrate inhibition kinetics. A second mechanism involves more than one substrate bound simultaneously to the active site. This kinetic mechanism was first proposed by Korzekwa *et al.* [76] to rationalize cytochrome P450 3A4 atypical kinetics. Active site occupation by multiple substrates results in a heterogeneous population of enzyme: Free enzyme (E), enzyme bound with a single substrate (ES), and enzyme bound with multiple substrates (ESS, etc.). The amount of each complex is dependent on the concentration of substrate and the relative substrate binding affinities for each complex. When the catalytic properties of ES differ from those of ESS (e.g., k_{cat} or rate of product release), atypical kinetics can be observed. In the SULT literature, evidence for the plausibility of this mechanism was found when a crystal structure of SULT1A1 was found to contain two molecules of 4-nitrophenol bound in the active site simultaneously [36]. These investigators postulated that overall rate of product formation from ESS was less than ES. Since ESS was formed at higher concentrations of substrate, the product formation curve displayed substrate inhibition as 4-nitrophenol concentration increased.

In addition, when SULT2A1 was cocrystallized with DHEA, two binding orientations were shown to exist for this substrate [85]. One binding orientation was consistent with a catalytic orientation (ES_1), while the other binding site penetrated further into the active site (ES_2); the authors postulated that this orientation might give rise to substrate inhibition [85]. Although different from multiple substrates within one active site, this mechanism would also result in two populations of bound enzyme (ES_1 and ES_2) with different product formation rates. Thus, as the concentration of substrate increases, it is expected that the ES_2 complex (in this case with reduced product formation) would be formed preferentially at higher concentrations of substrate, and consequently, at higher concentrations, substrate inhibition would characterize the product formation curve. On the basis of a kinetic argument, Gamage *et al.* [79] disputed this idea and proposed that the proportion of ES_1 and ES_2 complexes would most likely stay constant as substrate concentration increased and thus would not result in substrate inhibition. Finally, the stoichiometry of β -estradiol binding to human SULT1E1 was found to be 2:1 for each homodimer [66]. In this report, investigators noted that the binding of two molecules of estradiol to each

SULT1E1 subunit suggested that one of the binding sites was a catalytic site, whereas the other site could potentially be allosteric and regulate the turnover of the enzyme.

The allosteric binding site hypothesis was supported by studies with celecoxib, which in *in vitro* could modulate the stereoselectivity of ethinyl estradiol (EE) sulfation [86]. Celecoxib was first shown to cause product switching in SULT2A1-catalyzed sulfation of EE and then later with β -estradiol (E2) (from the 3-*O*-position to the 17 β -*O*-position) [86,87]. Detailed kinetics studies revealed that increasing concentrations of celecoxib decreased the $V_{\max}$ of EE 3-*O*-sulfation by three- to fourfold (without changing the K_m value significantly) and also increased the $V_{\max}$ and decreased the K_m for 17 β -*O*-sulfate formation by seven- and eightfold, respectively [86]. In addition, the inhibitory effect of celecoxib on EE 3-*O*-sulfation, as indicated by IC_{50} values, was independent of the EE concentrations. Increasing EE concentrations decreased the apparent kinetic constant for celecoxib (as indicated by EE 17 β -*O*-sulfation), suggesting that the formation of EE complex does not inhibit the binding of celecoxib. Collectively, these results lead to the conclusion that EE and celecoxib interacted with separate binding sites of SULT2A1 and the site bound by celecoxib could modulate the activity and regioselectivity of EE sulfation.

16.2.3.2 Practical Considerations. In a study conducted by Maiti *et al.* [88], it was shown that human SULT1E1 was inhibited in a time- and concentration-dependent manner by oxidized glutathione (GSSG) and that the redox status of Cys83 was implicated in affecting the enzyme activity. In this study, the presence of PAPS was found to have a protective effect against GSSG oxidative inactivation [88]. Moreover, these investigators also found that SULTs 1A1, 1A3, and 2A1 were not affected by redox conditions. Thus, it would appear that depending on the isoform, and perhaps the substrate, the redox state of key active site cysteine(s) may or may not influence SULT activity. Although the *in vivo* significance of this remains to be determined, the implications for *in vitro* experiments are clear. Investigators performing *in vitro* studies should be cautious to maintain reduced incubation/storage conditions, so as to more closely mimic the standard *in vivo* redox state.

Organic solvents have also been demonstrated to modulate SULT-mediated reactions [72]. In bench-top incubations, the presence of 0.4% (v/v) acetonitrile-activated SULT1E1-catalyzed 1-hydroxypyrene sulfation by ~ 2.6 -fold. When a two-site kinetic model was applied, studies demonstrated that acetonitrile affected $V_{\max 1}$, $V_{\max 2}$, and the K_i value of 1-hydroxypyrene sulfation, while there was no significant effect on the K_m value (the second binding site was postulated to be inhibitory and the binding constant was termed K_i). This suggests that solvent may potentially alter binding interactions of the second substrate molecule but not the first. Of course, there are other potential interpretations for this data; however, given the potential effects of organic solvents on SULT activities, it was recommended that ethanol should be used as the preferred solvent vehicle [72].

Divalent cations also have been shown to affect the activity of SULT enzymes. SULT enzymatic activity may be stimulated in the presence of both Mn^{2+} and Mg^{2+} . Using point-mutated SULT1A3 enzyme, Pai *et al.* [89] demonstrated that Mn^{2+} may exert a stimulatory effect by interacting with Glu86. Zhang *et al.* [66] found that Mg^{2+} stimulated SULT1E1 in a bell-shaped manner. Unfortunately, these findings were not supplemented with additional experimental work. In addition to SULTs, other drug-metabolizing enzymes are also affected by divalent cations. It has been recommended

that CYP3A4 incubations include Mg^{2+} , and in particular, since the free concentration of Mg^{2+} in liver is ~ 0.5 mM, it was suggested that incubations with CYP3A4 should include Mg^{2+} at a similar concentration [90]. By analogy, it may be necessary to include divalent cations in SULT incubations. However, the significance of cation inclusion, in terms of improving the ability to extrapolate *in vitro* data to *in vivo*, is not yet known.

Finally, careful attention to the amount of PAPS used in laboratory incubations is important. For example, the inhibition of 1-hydroxypyrene sulfation (using expressed SULT1E1) by mefenamic acid revealed that different inhibitory IC_{50} values could be obtained when different concentrations of PAPS were used in the incubation (data not published). In addition, when Kudlacek *et al.* [91,92] studied the sulfation of minoxidil, they reported a K_m value of 2.9 mM using a PAPS concentration of $0.4 \mu M$. In human platelets, Johnson and Baker [93] studied minoxidil sulfation and reported data using a concentration of $0.86 \mu M$ PAPS. The K_m value for PAPS has been reported to range from 0.16 to $0.66 \mu M$. However, the amount of PAPS in liver has been estimated to be ~ 17 – 77 nmol/g of tissue, or much higher than the concentrations used in the studies referenced above [33,37,66,94,95]. Saturation conditions for PAPS would be expected to be four to five times the K_m value or ~ 0.8 – $3.3 \mu M$. *In vivo*, it would appear that normal PAPS concentration is at a saturating level. Therefore, in laboratory incubations, it would be prudent to also use saturating PAPS concentrations to more closely estimate a relevant *in vivo* concentration and to avoid confounding kinetic results obtained when PAPS concentrations are no longer sufficiently above the K_m value. Moreover, it is important to ensure that sufficient amount of PAPS is used in kinetics experiments such that saturation of product formation observed at high substrate concentrations (e.g., 10 mM) is not an artifact caused by PAPS depletion.

16.2.4 Sulfation of Endogenous Substrates

In Section 16.1.4, the role of SULTs in fetal development was briefly discussed. In this section, other endogenous roles for SULT are explored. One such role is the sulfation of catecholamines. Catecholamines are mediators of physiological stress, and they prepare the body for physical activity. Some physiological responses include increased heart rate, blood pressure, and an increase in blood glucose levels [96]. Circulating levels of catecholamines, such as dopamine, are present primarily in the sulfated form and derive from the sulfation of dietary dopamine or sulfation of dopamine from the myenteric plexus [97]. In fact, the total circulating concentration of free dopamine was found to be less than 4% [98]. This observation is consistent with early experiments by Richter [99], who showed that the majority of orally administered epinephrine was excreted in urine as a sulfate conjugate. Also consistent is the observation that SULT1A3 is expressed at high levels in the intestinal tract (Section 16.1.3), which would contribute significantly to sulfated dopamine derived from the myenteric plexus.

The high level of SULT1A3 expressed in the intestinal tract has been suggested to serve as a “gut–blood” barrier [100]. This hypothesis is supported by the observation that fetal livers contain high levels of SULT1A3 levels, but that after birth (when exogenous dopamine levels will be obtained through the gastrointestinal (GI) tract) the expression of SULT1A3 is “turned off” in the liver [101]. Thus, while fetal livers contain significant SULT1A3 activity, adults do not. The capacity of SULT activity in

the GI tract appears to form a mechanism for detoxifying dietary biogenic amines in postnatal life, whereas the fetal liver takes on this role in prenatal life.

The two most abundant steroid sulfates present in plasma are DHEA and cholesterol. Blood concentrations of both can achieve low micromolar levels; however, unlike DHEA, cholesterol sulfate levels remain relatively constant throughout life [102]. Cholesterol sulfate is perhaps one of the more interesting sulfate conjugates because its physiological role and importance have been extensively studied. Initially, cholesterol sulfate was studied in the context of serving as a precursor for the synthesis of sulfonated steroids. The sulfate conjugate is a direct substrate for the synthesis of other adrenal steroids such as pregnenolone sulfate and DHEA sulfate, without removal of the sulfate moiety [103,104]. Moreover, cholesterol sulfate has also been shown to be a normal constituent of biological membranes (where it acts as a stabilizer) and a regulator of the activity of a number of enzymes (e.g., activating Factor XII, epidermal protein kinase C enzymes, etc.) [97,105,106]. Perhaps the most fascinating role that the sulfate conjugate serves is its involvement in keratinocyte differentiation and development of the epidermal barrier. Cholesterol sulfate conjugate is formed in the basal and spinous layer of the epidermis; these two layers are generally the lowest of the four to five skin layers that compose the epidermis [107,108]. Cholesterol reaches its highest concentration in the granular layer (third layer from the surface) and then concentrations decrease in the stratum corneum (first layer) because of increased sulfatase activity. Thus, sulfated cholesterol begins its journey through the epidermis in the lower layers, and as keratinocytes start to differentiate and migrate out to the surface, cholesterol sulfate is hydrolyzed by steroid sulfatase releasing free cholesterol, which is then available for conjugation in lower layers [107,108]. It has been hypothesized that this cycle plays an important role in normal desquamation (skin peeling or shedding) [109]. This idea is supported by the fact that patients with recessive X-linked ichthyosis, caused by steroid sulfatase deficiency, have difficulty (among other symptoms) with desquamation [110]. Finally, it is interesting that cholesterol is a substrate for SULT2B1_v2 (a splice variant of the *SULT2B1* gene) and that SULT2B1_v2 is significantly expressed in the granular layer, which, noted above, is the layer where cholesterol sulfate reaches the highest concentration [111].

16.2.5 Bioactivation

In the fields of drug metabolism and toxicology, bioactivation of compounds is a crucial topic that has been studied extensively [112,113]. The majority of the bioactivation processes are caused by cytochrome P450-mediated reactions that generate chemically reactive species, potentially leading to various types of toxicity. It has been shown that oxidative metabolites containing electron-deficient groups, such as epoxide and quinone/quinone imine/quinone methide, can form DNA adducts and eventually cause mutagenicity and genotoxicity [114–116]. Sulfation, as it turns out, is another bioactivation mechanism that can generate mutagenic products [117,118]. Sulfate conjugates of *N*-hydroxy aromatic amines (e.g., *N*-hydroxy-acetylaminofluorene) undergo N–O cleavage to form reactive nitrenium ions (Fig. 16.3), resulting in subsequent formation of DNA adducts and gene mutations in bacteria and mammalian cells [119,120]. Similarly, carbocations have been identified to be the reactive species generated from sulfation products of polycyclic benzylic alcohols (e.g., 1-hydroxymethyl pyrene) and allylic alcohols (e.g., 1'-hydroxyestradiol) [121,122]. Note that the positive charge of

Figure 16.3 Bioactivation of sulfonate conjugates via the formation of reactive nitrenium and carbocation intermediates. Nu, nucleoside.

carbocation/nitrenium is stabilized by the conjugated system as evidenced by DNA adducts with alternative adduction sites arising from resonance structures. Mutagenicity observed from *in vitro* systems has been shown to be compound-dependent and SULT isoform-dependent [117,118]. It has been hypothesized that tissue expression and genetic polymorphism of a particular SULT isoform may influence the genotoxic effects of a given promutagen or procarcinogen. Further evaluations using humanized animal models have been proposed to gain insights on this matter.

16.3 CLINICAL PERSPECTIVES

16.3.1 Polymorphisms

Pioneer studies conducted by Eichelbaum *et al.* and Mahgoub *et al.* in the 1970s illustrated that the reduced metabolism of sparteine/debrisoquine was caused by deficiency of a single gene (now known as *CYP2D6 polymorphism*) [123]. Since then, genetic polymorphisms have been studied for CYPs [124] as well as other drug-metabolizing enzymes such as glutathione *S*-transferases [125], *N*-acetyltransferases [126], UDP-glucuronosyltransferases [127,128], and SULTs [18,129–134].

Polymorphism of SULT1A1 is the most extensively studied among various SULT enzymes. A number of single nucleotide polymorphisms (SNPs) have been identified for *SULT1A1* gene, however, only a few of these SNPs are located at the coding region and affect the amino acid sequence (nonsynonymous cSNPs). *SULT1A1**2 allele, the most common allelic variant other than *SULT1A1**1 allele (wild type), has a G→A mutation at nucleotide 638 in the coding region, resulting in an arginine to histidine substitution at amino acid 213 (Arg213His). By measuring SULT1A1 activity

in human platelet cells with 4-nitrophenol as a probe substrate, individuals homozygous for the *SULT1A1**2 allele were shown to have ~15% of the enzyme activity of *1A1**1/*1A1**2 heterozygotes or *1A1**1 homozygotes [132]. The lower enzyme activity of *SULT1A1**2 allozyme appears to result from, at least in part, preferential degradation via the proteasome pathway as compared to *SULT1A1**1 [133]. The second most common *SULT1A1* SNP is A667G, leading to amino acid substitution Met223Val. This variant is termed *SULT1A1**3. Kinetics studies showed that *SULT1A1**3 allozyme generally exhibits lower K_m and higher V_{max} values for various substrates when compared to the wild-type enzyme. Ethnic variation in allele frequencies for *SULT1A1**2 and *SULT1A1**3 has been reported [130,134]. For *SULT1A1**2, the frequency was higher in Caucasian (0.254–0.365), African (Nigerian and African-American; 0.269–0.294), and Turkish (0.238) than Japanese (0.168), Chinese (0.045–0.110), Korean (0.116), and Egyptian (0.135) populations. Interestingly, *SULT1A1**3 allele is highly prevalent in African-Americans (frequency 0.229). It is detected in low frequency in Caucasians (0.000–0.029) and is virtually absent in other ethnic groups.

Nonsynonymous SNPs have also been identified for *SULT1E1* and *SULT2A1* [18,129–131]. Three SNPs (G64T, C95T, and C758A) were observed in *SULT1E1*, resulting in amino acid changes Asp22Tyr, Ala32Val, and Pro253His, respectively. These variants appear to be very rare (allele frequency 0.008) in Caucasians and African-Americans combined. Although the Val32 (*SULT1E1**2) allozyme has similar affinities for β -estradiol and cofactor PAPS relative to the wild-type allozyme, the K_m values determined for Tyr22 and His253 allozymes are significantly higher. For *SULT2A1*, nonsynonymous polymorphisms (A63P, K227D, and A261T) have been identified in African-Americans but not in Caucasian Americans or Japanese. Allozymes expressed in COS cells generally showed decreased enzyme activities and lower immunoreactive protein levels. Surprisingly, the Tyr261 allozyme, resulting from a G→A mutation at nucleotide 781, appears to be a monomer rather than dimer. Despite that difference, the Tyr261 and the wild-type allozymes display comparable affinities for DHEA and PAPS. The allelic frequency for the G781A variant is 0.101–0.144 in different African-Americans populations.

It is important to point out that polymorphisms observed in SULTs have not been reported to significantly alter the elimination of drugs [135,136]. This is likely due to the fact that virtually all drugs undergo sulfation also having alternative elimination pathways such as direct excretion, oxidation, and glucuronidation.

16.3.2 Induction

Many xenobiotics act as perpetrators in pharmacokinetics drug–drug interactions by inducing drug-metabolizing enzymes, which results in an increased elimination of the victim compounds [137,138]. Elevation of drug-metabolizing enzymes usually begins at the transcriptional level when nuclear receptors are activated by the binding of chemical inducers. In the case of CYP enzymes, nuclear receptors such as aryl hydrocarbon receptor (AhR), pregnane X receptor (PXR), constitutive androstane receptor (CAR), glucocorticoid receptor (GR), peroxisome proliferator-activated receptor (PPAR), liver X receptor (LXR), and farnesoid X receptor (FXR) have been shown to regulate enzyme expression levels. *In vitro* studies conducted in primary human hepatocytes indicated that activation of AhR, PXR, CAR, LXR, and FXR did not significantly induce mRNA expression of various SULTs [139–141]. In fact, repression of gene expression was

observed for *SULT1E1* and *SULT2A1* in human hepatocytes treated with rifampicin [141,142], a known ligand for human PXR. Such repression was shown to be mediated by hepatocyte nuclear factor 4 α . Human hepatocytes treated with dexamethasone and ciprofibrate, prototypical ligands for GR and PPAR α , respectively, led to increases in *SULT2A1* mRNA and protein levels [140,143]. However, the clinical significance of *SULT2A1* induction remains to be determined.

16.3.3 Reaction Phenotyping

Identification of drug-metabolizing enzymes responsible for the biotransformation of a new drug (new chemical entity, NCE) is a necessary and pivotal study in the drug discovery and development process. The results of these studies, usually referred to as *reaction phenotyping studies*, are utilized to evaluate several issues: the potential of the NCE to be involved in a potential drug–drug interaction via inhibition of the enzyme(s) responsible for NCE metabolism; evaluation of the effect of induction on the NCE metabolism; and finally, the possible effects of genetic polymorphism of NCE metabolism. Although the historical focus of reaction phenotyping studies has focused on CYP enzymes, there is an increasing effort in recent years to characterize biotransformations catalyzed by non-CYP enzymes such as SULTs [29,70,75,144,145].

It has been well established for CYP enzymes that the reaction phenotyping studies generally consist of (i) correlation analyses utilizing a bank of individual tissue preparations characterized for enzyme activities; (ii) kinetic determinations with recombinant enzymes and tissue preparations; and (iii) inhibition experiments using isoform-selective chemical inhibitors and/or antibodies [146]. In the authors' experience, the last method is by far the most commonly used in industry. Attempts have been made to adopt these approaches for SULT enzymes; however, the success appears to be handicapped by limited knowledge and/or reagents available.

Correlation analysis involves the comparison of the interindividual variability of the sulfation rate of interest with the previously determined activity or protein level of a given SULT isoform. Hence, in order to determine SULT isoform enzymatic activity, the availability of SULT-isoform-selective probe substrates is vital to the correlation approach. Reasonably good correlation between protein expression and enzyme activity was observed for *SULT1A1*, *SULT1E1*, and *SULT2A1* (using 4-nitrophenol, β -estradiol, and DHEA as probe substrates, respectively) in human liver cytosol ($r \sim 0.64\text{--}0.86$) [43]. However, a selective probe substrate for *SULT1B1* has not been identified to-date. Apart from this, the fact that SULTs usually have overlapping substrate specificities [70,145,147] make correlation studies challenging and the results difficult to interpret. As such, the correlation approach has not been widely used for SULT phenotyping.

Screening of sulfate conjugation with recombinant SULT enzymes has been commonly employed as the initial approach, facilitated, at least in part, by the commercially available SULT enzymes (*SULT1A1*, *SULT1A3*, *SULT1E1*, and *SULT2A1*) representing the majority of isoforms detected in human liver and GI tract [43]. Kinetic studies are then conducted in recombinant enzymes and in tissue preparations to determine the affinity for the substrate (K_m) and the type of kinetics (e.g., hyperbolic vs substrate inhibition). Since the substrate affinity for a single enzyme should be similar regardless of the source/preparation (ideally), comparison of the K_m values determined in recombinant enzymes with that obtained in tissue preparations provide additional evidence

in identifying the SULT enzyme(s) responsible for the sulfation reaction observed in tissue.

Inhibition studies represent a primary methodology for reaction phenotyping. In particular, isoform-selective chemical inhibitors and/or immunoinhibitory antibodies allow direct quantitative assessment of the contribution of individual isoforms at a given drug concentration (often the concentration used is physiologically relevant), as exemplified in a countless number of CYP-mediated biotransformations. Unfortunately, isoform-selective inhibitory antibodies for SULTs are not yet commercially available. 2,6-Dichloro-4-nitrophenol (DCNP) is a potent inhibitor of SULT1A1 ($IC_{50} < 0.1 \mu M$) with selectivity of more than 2 orders of magnitude over SULT1A3, SULT1B1, SULT1E1, and SULT2A1 [144,148–150]. The compound is suitable to be utilized as a SULT1A1-selective inhibitor in human liver and GI preparations. Apart from DCNP, there has not been any other isoform-selective inhibitor reported for SULTs. It has been suggested that an ortho-hydroxy-polychlorinated biphenyl (6'-OH-PCB) could potentially serve as a specific inhibitor of SULT1B1 [151]. However, inhibition results in this study may have been confounded by substrate inhibition, poor inhibitor/substrate solubility, as well as the use of a substrate concentration (3-hydroxybenzo[a]pyrene) that was ~6-fold greater than the reported K_m value for SULT1A1*1, and ~20-fold lower than the reported K_m for SULT1B1 [152]. Because 6'-OH-PCB may serve as an isoform-selective inhibitor, further experiments to confirm the inhibition of SULT1B1 would be useful. In addition, compounds such as quercetin and estrone could also serve as probe inhibitors but further experiments are needed [75,144]. At $1 \mu M$, quercetin strongly inhibited sulfation activities catalyzed by recombinant SULT1A1 and SULT1E1 but had no effect on SULT1A3 and SULT2A1 activities. Similarly, estrone (at 40 nM) greatly inhibited (>75%) SULT1A3 and SULT1E1 activities but had minimal effect on SULT1A1 and SULT2A1 activities. Caution should be exercised when interpreting inhibition results obtained with quercetin and estrone as their inhibitory effects on SULT1B1 and other SULT enzymes have not been examined. Overall, reaction phenotyping for SULTs can be performed to some extent, and the quality will certainly improve when additional reagents become available in the future.

16.3.4 Drug–Drug Interactions

A large number of *in vitro* studies have been published, which suggest potential *in vivo* SULT drug–drug interactions. However, there are few confirmed *in vivo* drug interactions that are mediated by this class of enzymes. Moreover, as noted above, polymorphisms affecting SULT activity (which can mimic chemical inhibition) have not been clearly associated with significant changes in drug elimination [135,136].

The most commonly published example of a SULT-mediated drug–drug interaction involves an indirect mechanism. In humans, a single dose of acetaminophen (1.5 g) has been shown to cause partial depletion of inorganic sulfate [153]. This observation is relevant to SULT drug–drug interactions because the level of inorganic sulfate affects the level of PAPS [154,155]. The activity of all SULT reactions depend on the availability of PAPS as a cofactor, which in turn is dependent on the rate of PAPS synthesis and degradation [156]. Cellular uptake of inorganic sulfate depends on two uptake mechanisms: one is Na^+ independent and the other is Na^+ dependent [157–159]. Once uptake has occurred within the cell, PAPS is synthesized from inorganic sulfate by what is thought to be a bifunctional protein, associated with ATP-sulfurylase and adenosine

5'-phosphosulfate kinase activities [160]. Thus, indirect drug interactions can occur through a variety of mechanisms. To illustrate one mechanism, the concomitant administration of acetaminophen and a compound that undergoes significant sulfation can potentially lead to a competitive interaction in which a capacity-limited pool of PAPS is depleted by sulfation of one or both drugs [161–163]. In addition, other mechanisms may also include the inhibition of transporters involved in the cellular uptake of inorganic sulfate, or inhibition of PAPS synthase itself [156]. In the case of acetaminophen where doses are high (on a milligram per kilogram basis), competition for and depletion of the PAPS pool has been hypothesized as the mechanism behind interactions with fenoldopam and EE [164,165]. However, a study conducted in healthy male volunteers showed that codosing acetaminophen with troglitazone resulted in no statistically or clinically relevant differences in troglitazone exposure area under the plasma drug concentration-time curve ($AUC_{0-\infty}$) [166]. Troglitazone is metabolized to a sulfate conjugate, a glucuronide conjugate, and an oxidative quinone metabolite. Under steady state conditions, the AUC of the sulfated metabolite was 7–10 times greater than that of parent, whereas quinone exposure was similar to parent. The glucuronide was a minor metabolite (20–40% of parent) [167]. Thus, sulfation represented a major pathway for troglitazone metabolism, yet the coadministration of acetaminophen did not affect exposure. In fact, when troglitazone and acetaminophen were concurrently administered only a slight decrease in the troglitazone sulfate metabolite was observed; the decrease was not judged to be clinically relevant [166].

In addition to an indirect mechanism, SULT-mediated drug–drug interactions may result from a more traditional mechanism where a single SULT serves as the locus of the interaction. One example of this is the interaction of etoricoxib with EE. EE is a primary active component used in many oral contraceptive (OC) formulations; the metabolism of EE is complex, involving cytochrome P450, glucuronosyltransferases and SULT [168]. The absolute oral bioavailability of EE is variable and ranges from 20% to 65% [169]. In urine, the major metabolites excreted are glucuronides (up to 85%) followed by sulfate conjugates (up to 19%) and then low levels of monooxidation products [170]. Because more than one enzymatic pathway is involved in EE metabolism it would be expected that EE should be relatively resistant to drug–drug interactions. However, EE is subject to significant gut first-pass metabolism, and it has been shown that up to 38% of the EE dose forms conjugates in human jejunal mucosa and ~90% of the conjugates can be hydrolyzed by sulfatase [171]. These results imply that sulfation of EE is considerable in the GI tract and may be a major factor affecting bioavailability. As a consequence, it has been postulated that inhibition of SULTs in the GI can serve as a locus for drug–drug interactions, affecting the bioavailability of EE [172]. In support of this hypothesis, acetaminophen was orally administered 1 h before OC administration and subsequently, the pharmacokinetics of EE demonstrated that AUC_{0-24} was increased 22% [165]. It was hypothesized that the bioavailability of EE increased in response to depletion of the PAPS pool. Interestingly, although the investigators in this study did not report C_{max} values of EE, the C_{max} appears to have increased 60–70%. This increase in C_{max} was consistent with the hypothesis of lower intestinal SULT activity, which then resulted in increased absorption from the gastrointestinal lumen.

In an example of a direct drug–drug interaction caused by SULT inhibition, etoricoxib has been reported to inhibit EE sulfation activity catalyzed by SULT1E1, the major SULT isoform catalyzing the sulfation of EE [144]. It was further hypothesized

that after an oral dose, the high local intestinal exposures of etoricoxib could interfere directly with first-pass sulfation of EE via inhibition of SULT1E1. Evidence for this inhibition was published later by an *in vivo* drug–drug interaction study involving EE and etoricoxib. Data presented within this report show that coadministration of EE with etoricoxib was associated with a 50–60% increase in EE exposure, and a decrease of EE-sulfate exposure by ~40% [173].

16.4 CONCLUSIONS AND FUTURE PROSPECTS

SULTs are an important class of enzymes and are involved in many endogenous processes such as estrogen biosynthesis, influencing receptor-active thyroid hormone levels and sulfation of catecholamines and steroids (e.g., DHEA or cholesterol). For drug metabolism scientists, sulfation is of interest because it can potentially lead to electron-deficient species, and therefore, it is important to be aware of potential structural alerts that may increase the risk of SULT-mediated reactive intermediates. However, relative to other drug-metabolizing enzymes, SULT-mediated elimination of therapeutic compounds is rather limited; for this reason, and others, the contribution of SULTs to drug metabolism has been underappreciated, particularly in industry. With increased availability and use of high quality hepatocytes, the importance of SULTs to drug metabolism will become more evident in the future. As a result, drug metabolism scientists will be faced with many challenges. Foremost is the lack of a “chemical toolbox” to study SULT isoform involvement in drug elimination. While reaction phenotyping is readily accomplished with cytochrome P450s, there is no panel of well-characterized SULT-isoform-specific inhibitors. During the course of determining the mechanism for a clinical drug–drug interaction of etoricoxib with ethinyl estradiol, the authors of this chapter screened several hundred compounds in an effort to obtain specific inhibitors for a number of SULT isoforms (unpublished). This effort was largely unsuccessful. Thus, approaches other than screening (such as rational design from crystallography/computational chemistry) may have to be utilized to efficiently generate isoform-specific inhibitors.

The literature contains several examples of isoform-specific or isoform-selective SULT substrates, but the characterization of those substrates against all the relevant SULT isoforms is often lacking. As a consequence, the study of SULT inhibition and/or induction is hampered by the ambiguity surrounding the use of “probe” substrates. In the future, the discovery, development, and characterization of a panel of isoform-selective inhibitors and substrates will greatly increase the success of metabolism studies during drug discovery and development. Increased success in this area will also serve to further highlight the importance of this class of enzymes in drug metabolism [97,98].

17.1 SUMMARY

The glutathione transferase (GST) superfamily contains a number of enzymes that catalyze the conjugation of glutathione (GSH) to a wide range of compounds of both endogenous and exogenous origin. In addition to catalytic reactions, the GSTs also modulate several cell signaling kinases and ion channels such as Jun N-terminal kinase (JNK) and ryanodine receptors via protein/protein interactions. Pharmacogenetic studies have identified variations in drug response and susceptibility to cancer and other disorders associated with variant GST isoforms. In humans, the cytosolic GSTs have been subdivided into seven distinct classes termed *Alpha*, *Mu*, *Pi*, *Theta*, *Sigma*, *Zeta*, and *Omega*, and there are multiple genes in some classes. So far, 48 allelic variants that cause amino acid substitutions have been documented, and in many cases, the variant proteins have been functionally and structurally characterized. Common deletions of the *GSTM1* and *GSTT1* genes have been extensively investigated in relation to cancer susceptibility and drug response, and they have also been the subject of a vast number of disease association studies. Some polymorphisms in promoter regions have been shown to affect the level of GST expression *in vitro* and *in vivo* and this area requires further investigation.

The various members of the GST superfamily are characterized by striking differences in the reactions they catalyze and their substrate specificities. The structures of

representatives of all the human GST classes have been determined by X-ray crystallography and their differing reaction mechanisms have been investigated by mutagenesis and functional studies.

17.2 INTRODUCTION

The GST superfamily contains a number of enzymes that catalyze the conjugation of GSH to a wide range of compounds of both endogenous and exogenous origin. The GSTs have been intensively studied because of their capacity to protect cellular components from attack by electrophiles, and consequently, they have been implicated in the development of drug resistance and susceptibility to carcinogens. Pharmacogenetic studies have identified variations in drug response and susceptibility to cancer and other disorders associated with variant GST isoforms. A review by Hayes and Pulford [1] provides an excellent summary of the types of environmentally derived compounds that are conjugated or transformed by the action of GSTs. In addition, the Comparative Toxicogenomics Database provides an extensive compilation of publications reporting chemical/GST/disease interactions [2]. GSTs contribute to around 10% of the cytosolic protein in rat liver, and as they can be detected as discrete bands on coomassie blue stained SDS-PAGE gels of liver cytosol, it seems likely that GSTs are involved in additional physiological processes. An early study noted the identity of a rat GST with “ligandin,” a protein known for its capacity to bind a range of hydrophobic compounds, including carcinogenic azodyes, corticosteroids, and bilirubin [3,4]. In recent years, it has been shown that the physiological roles of GSTs extend well beyond the disposition of xenobiotics and include both enzymatic and nonenzymatic functions. Some GSTs catalyze cis–trans isomerase reactions that are important in steroid hormone synthesis and the catabolism of tyrosine [5–7], while others protect cells against the products of lipid peroxidation by catalyzing the reduction of lipid hydroperoxides [8] or the conjugation of reactive α,β -unsaturated carbonyl compounds such as 4-hydroxy nonenal [9–11]. In addition, GSTs have been identified, which catalyze thioltransferase reactions and the reduction of biologically significant molecules such as dehydroascorbate [12,13]. Members of the GST superfamily have been shown to engage in protein–protein interactions that can have a direct effect on several signaling pathways. The stress-activated kinase Jun N-terminal kinase, apoptosis-stimulating kinase 1 (ASK1), and tumor necrosis factor (TNF) receptor-associated factor 2 have all been shown to be modulated by GST binding [14–16] and there is evidence that Fanconia anemia group C protein (FANCC) can modulate the activity of GSTP1-1 during apoptosis [17]. A number of studies have shown that the chloride intracellular channel (CLIC) proteins are members of the GST superfamily and can enter membranes to form or modulate ion channels [18–21]. The human muscle-specific GST, GSTM2-2, has been shown to be a potent inhibitor of the cardiac ryanodine receptor Ca^{2+} channels and may play a key role in modulating excitation contraction coupling in the heart [22–24].

GSTs and GST-like proteins are almost ubiquitous in nature and there are close to 30,000 papers concerning GSTs listed in PubMed. Many aspects of this large field have been extensively reviewed [1,8,25–37]. This chapter focuses on the genetic variation in the human GSTs and its impact on their structure and function.

17.3 THE GST GENE FAMILIES

The evolutionary history of the GSTs is complex. Phylogenetic analysis has shown that at least four families of proteins with GST activity have emerged by convergent evolution [38]. In mammals, there are three well-recognized structurally and genetically distinct families of proteins that catalyze GST reactions. These families have been generally termed the *cytosolic*, *microsomal*, and *mitochondrial GSTs* [8,33,39–41]. The cytosolic GSTs are a large multiclass family of proteins that share a common structural fold and an ability to catalyze a variety of GSH-dependent reactions. Classically, they have been studied as drug and xenobiotic detoxication enzymes, conjugating GSH to small hydrophobic molecules in phase II drug metabolism reactions. However, as the number of members of this gene family has expanded with the genome era, so has the type of reactions and functions associated with these proteins. The membrane-bound microsomal GSTs have also been termed the *membrane-associated proteins in eicosanoid and glutathione metabolism* (MAPEG) [39]. There are at least six members of this family in humans, and although most have the capacity to conjugate GSH to 1-chloro-2,4-dinitrobenzene (CDNB), they appear to play prominent roles in the synthesis of leukotrienes and prostaglandins *in vivo* [39]. Although some cytosolic GSTs are also found within mitochondria, the Kappa class GST is found specifically within mitochondria and peroxisomes [42]. There is a single Kappa class gene in humans, rats, and mice and their amino acid sequences show little identity with the cytosolic or MAPEG GST families. Although the structure of the Kappa class GSTs contains a thioredoxin fold domain that is reminiscent of the cytosolic GSTs, it contains a polyhelical domain embedded in the linear sequence between the N-terminal region β -strands [40,41]. This contrasts with the cytosolic GSTs where the α -helical domain is encoded entirely within the C-terminal sequence (Fig. 17.1). This difference in structure suggests that the Kappa class GSTs also evolved via a distinct but convergent evolutionary path.

17.4 THE CYTOSOLIC GSTs

17.4.1 A Historical Perspective

This chapter focuses primarily on the cytosolic GSTs as they are considered to be of most significance in drug and xenobiotic metabolism. Originally, multiple cytosolic GSTs were identified by the reactions they catalyzed, their elution profile from ion

Figure 17.1 Topology diagrams comparing the secondary structural organization of cytosolic GSTs with the Kappa class GST [41,43]. β -Strands are shown as arrows and α -helices are shown as rectangles.

exchange chromatographic columns, their molecular weight, their isoelectric point, and their native electrophoretic mobility [44–47]. These and many other studies led to the development of a range of largely laboratory-specific nomenclature systems that are quite confusing to new readers of the older literature. Although there was early evidence that some GST isoenzymes had other substrate preferences [45,48,49], most GSTs were found to utilize CDNB as a substrate. The discovery of GSH affinity chromatography and the use of CDNB as a substrate allowed the biochemical characterization of many GSTs; however, this focus also delayed the discovery of GSTs that do not bind to GSH affinity matrices and do not use CDNB as a substrate [50–52]. The discovery and characterization of the Theta, Zeta, Omega, and CLIC proteins in mammals came from the utilization of different substrates and the use of bioinformatics to analyze sequence databases [12,18,53,54]. The discovery of novel GSTs by the use of bioinformatics subsequently presented an interesting challenge to identify their substrates.

17.4.2 Classification of the GSTs

The confusion in GST nomenclature was resolved in the early 1990s. The cytosolic GSTs were classified into a number of different classes that are designated by the Greek alphabet. The classes were originally defined in humans, rats, and mice on the basis of their amino-terminal sequence and their antigenic identity. An international nomenclature convention has been established that is theoretically extendable to other species [55,56]. Readers should refer to these reports for a definitive description of the accepted nomenclature system. Seven distinct classes have been well characterized in mammals and have been termed *Alpha*, *Mu*, *Pi*, *Theta*, *Sigma*, *Zeta*, and *Omega*. Proteins in each class are termed by the initial letter of the class name. For example, GSTA1-1 specifies the homodimeric product of the Alpha class *GSTA1* gene and GSTA1-2 specifies the heterodimeric product of the *GSTA1* and *GSTA2* genes. Other mammalian proteins that share the same structural fold but have no known enzymatic activity have been identified but not formally classified as GSTs. These include the CLIC family of proteins that have been shown to form chloride channels and to modulate the activity of ryanodine receptor Ca^{2+} channels in muscles [18]. In addition, molecular models of ganglioside-induced differentiation-associated protein 1 (GDAP1) and its paralog GDAP1-like 1 (GDAP1L1) suggest that they have a GST fold, but they appear to be inactive with common GST substrates [57,58]. Although the role of GDAP1 has not been clearly defined, mutations in GDAP1 have been shown to cause a severe recessive form of Charot–Marie–Tooth disease [59,60].

A range of additional classes and GST-like enzymes have been specifically defined in other evolutionary orders, including the Delta and Epsilon classes in insects [61,62]. In plants, Phi, Tau, and Lambda classes have been described together with a dehydroascorbate reductase class that has not been assigned a Greek letter [63]. Numerous GSTs have been identified in different microbial species, and although many show sequence or functional similarities with mammalian GSTs, the class boundaries are indistinct [64–66]. The Zeta class is the most widely conserved class and has been reported in species from bacteria through to plants, fungi, insects, fish, birds, and mammals. The conservation of the Zeta class is probably because of its isomerase activity converting maleylacetoacetate to fumarylacetoacetate in the catabolism of tyrosine [6,54,67]. While the Zeta class has been both structurally and functionally conserved across evolutionary time, some GST classes have developed highly specialized functions while

maintaining structural conservation between species. Possibly the most striking functional divergence has occurred in the Sigma class GSTs that catalyze prostaglandin D₂ synthesis in mammals and act as lens crystallins in squids [68,69].

17.4.3 GST Function and Nomenclature

Historically, and in accordance with the accepted nomenclature system [70], GSTs have been assigned a number within each class (GSTA1-1, GSTA2-2, etc.) in order of their discovery. Since many of the duplication events that have generated the multiplicity of GSTs in specific classes have occurred independently in different species (see below), it unfortunately follows that GSTs that are members of a specific class and have been assigned the same number may have different catalytic functions and show significant differences in their regulation in different species. For example, human GSTA3-3 has specific steroid isomerase activity and potentially plays a significant role in steroid hormone synthesis [5]. However, mouse GSTA3-3 is an efficient conjugator of aflatoxin B1 and has low steroid isomerase activity [71]. This functional difference in the GSTA3-3 isoenzymes in humans and mice accounts for the relative resistance of mice to aflatoxin carcinogenesis compared with humans. In contrast, the GSTA4-4 isoenzymes are paralogous in mice and humans, as they both have high specific activity in the conjugation of 4-hydroxynonenal an endogenous product of lipid peroxidation [10,11]. As a result of these differences, care should always be taken in ascribing GST function on the basis of nomenclature.

17.5 CYTOSOLIC GST GENES

A summary of the human cytosolic GSTs and their corresponding genes is provided in Table 17.1. GST classes may include multiple genes and the number of enzymes expressed in each class can vary between species. For example, there are two Pi class and three Theta class GSTs in mice but only one Pi and two Theta class GSTs in humans. In humans, the genes that encode GSTs from each class are grouped into clusters on different chromosomes, indicating the role of gene duplication in generating the diversity that is apparent within many GST classes. A similar arrangement generally occurs in mice and rats but the mouse *GstA3* gene is known to occur on chromosome 1 and has been separated from other Alpha class genes that are located on chromosome 9 (Board and Liu, unpublished data) [72]. The GST genes in humans are relatively small in size most falling between 3 and 17 kb in length and are composed of five to nine exons (Table 17.1).

17.5.1 Human GST Pseudogenes

There are many GST pseudogenes within the human genome. Some are intronless and are derived from reverse transcripts of mRNA that have been inserted randomly in the genome. Intronless GST genes have been reported in *Drosophila melanogaster*, [110] but there is no evidence that any reverse-transcribed GST sequences in the human genome are transcribed and translated into protein. In contrast, there are numerous pseudogenes and gene fragments within the different classes of gene clusters [73,102]. These are further evidence of the on going role of gene duplication and gene conversion

in the evolution of diversity within the class-specific GST gene clusters in different species. The Alpha class in humans provides an example of this diversity and the problems that can be associated with differentiating genes and pseudogenes. Normally, it is evident that a gene is functional if a corresponding mRNA can be identified. However, if a gene is only expressed transiently in highly specialized cells, it can be difficult to detect the complementary DNA (cDNA). Several studies have noted a number of pseudogenes and gene fragments within the human Alpha class gene cluster on the short arm of chromosome 6 [73,74]. One gene sequence putatively identified as *GSTA5* appeared to be complete with no frame shifts, premature stop codons, deletions or insertions, and acceptable intron/exon boundaries [73]. Although no evidence of the expression of this gene has been found, a recent study has shown that if the gene is driven by a heterologous CMV promoter, fully spliced mRNA and catalytically active enzyme can be expressed in HEK-293 cells [82].

17.5.2 Alternative Splicing of GST Transcripts

Alternative splicing of GST mRNAs is a potential source of variation that is significant in some other drug and xenobiotic metabolizing enzymes such as the UDP-glucuronosyltransferases but does not appear to generate functional diversity among the mammalian GSTs. Although alternative transcripts of human *GSTM4* [92] and *GSTT1* [111] and mouse *Gsto1* and *Gsto2* [107] have been reported, and bioinformatics studies on expressed sequence tags readily detect alternative splicing in other GSTs [112], there is no evidence at this stage that alternative transcripts give rise to variant GST proteins in mammals. In mice, several alternative *Gsto2* transcripts containing different 5' noncoding exons have been detected in EST databases and there are significant differences in the transcript size in different tissues suggesting that alternative splicing in 5' noncoding regions may be important in regulating expression in particular tissues or conditions [107]. In the parasitic nematode *Onchocerca volvulus*, alternative splicing of the Omega class GST Ov-GST3 may be dependent on a stress response [113]. In contrast to humans and mice, alternative splicing has been exploited extensively in insects to generate functional diversity that has implications in the development of insecticide resistance. Alternative splicing in the GST family has been reviewed recently by Wongsantichon and Ketterman [112].

17.6 GENETIC POLYMORPHISM OF HUMAN GST GENES

In addition to the variation in the GST family inherent in the number of classes and the variable number of gene loci within each class, a further layer of heterogeneity results from deletions and single nucleotide polymorphisms (SNPs). Genetic polymorphism can occur in coding and noncoding regions and can significantly modify gene expression and the function of the expressed enzymes. Genetic polymorphism can therefore result in individual differences that can have an impact on drug and xenobiotic metabolism. Some polymorphisms are common and are found in most populations, while others are rare and can be restricted to specific ethnic groups. A survey of PubMed reveals in excess of one thousand papers investigating the possible association of specific GST polymorphisms with a wide range of disorders that may be influenced by variations in the metabolism and disposition of drugs and other environmentally derived carcinogens and toxins. The validated polymorphisms in human GSTs that alter the amino acid sequence or have a direct impact on the expression, structure, and function of human cytosolic GSTs are provided in Table 17.2.

17.6.1 The Alpha Class

An excellent review of the genetic polymorphisms in the Alpha class GST genes has been published [114].

17.6.1.1 *GSTA1*. So far there are no validated SNPs in the coding region of *GSTA1* which cause an amino acid substitution. A single SNP (A375G) that is highly polymorphic in Europeans, Africans, and Asians has been detected, but it is synonymous and does not change the K75 residue [128]. Several linked SNPs (G-52A, C-69 T, C-115 T, T-567G, T-631G, and C-1142G) have been validated in the 5' noncoding region

and analyzed in different haplotypes [129–131]. The most significant 5' SNP appears to be a G-52A substitution in an SP1 response element where the G allele increases reporter gene expression around fourfold in HepG2, GLC4, and Caco-2 cell lines [73]. The homozygous presence of this allele in the proposed *hGSTA1**A haplotype (G-52, C-69, and T-567) was associated with fourfold higher levels of GSTA1-1 protein in the liver than in *hGSTA1**B (A-52, T-69, and G-567) homozygotes [129]. While this finding indicates that the G-52A has a significant effect on GSTA1-1 expression in the liver, similar differences were not found in the pancreas [132], suggesting that the effect of this polymorphism on gene expression may be tissue specific. The frequency of the *hGSTA1**A haplotype containing the G-52 allele ranges between 0.6 and 0.85 in African, Asian, and Caucasian populations.

17.6.1.2 *GSTA2*. A total of four nonsynonymous SNPs that result in the substitutions P110S, S112T, K196N, and E210A have been detected in the coding sequence of *GSTA2* [128,133,134]. These SNPs occur in five haplotypes termed *GSTA2**A–*GSTA2**E (Table 17.2). However, the K196N substitution that gives rise to the *GSTA2**D haplotype has only been observed in two EST database sequences and has not been confirmed in any population studies [133]. Consequently, it is unclear if this variant exists or is the result of a DNA sequencing error.

The E210A and S112T substitutions that are represented in haplotypes *GSTA2**B and *GSTA2**C do not appear to have any significant effect on catalytic activity [128]. In contrast, the rare P110S substitution that occurs in haplotype *GSTA2**E has diminished activity with several substrates, including CDNB and organic hydroperoxides, but elevated activity toward 4-nitrophenylacetate [133,134]. A recent study has shown that the *GSTA2**E variant has very high catalytic efficiency with azathioprene [135]. Azathioprene is used clinically in the treatment of cancer and some autoimmune disorders and a low activity allelic variant of thiopurine methyltransferase has been associated with toxicity resulting from the accumulation of high levels of 6-mercaptopurine [136]. The inheritance of the *GSTA2**E variant may also cause the liberation of high concentrations of 6-mercaptopurine and contribute to azathioprene toxicity.

Quantitative studies on *GSTA2*-2 protein in human liver samples have shown that the presence of the T112 substitution (*GSTA2**C) causes a significant reduction to levels that are around 25% of those associated with the other haplotypes [134]. The cause of the apparently poor expression of the *GSTA2**C subunit is not clear. The possibility that the T112 substitution causes protein instability or sensitivity to degradation seems unlikely but has not been tested. It seems more likely that the SNP is linked to another SNP that directly affects gene expression.

17.6.1.3 *GSTA3*. *GSTA3*-3 in humans plays a highly specialized role in the isomerization of Δ^5 -3-ketosteroids in the synthesis of testosterone and progesterone. So far only a single SNP in the coding region of *GSTA3* has been validated and characterized [115]. This SNP results in an I71L substitution and has only been identified in African subjects. Recombinant *GSTA3*-3 with the L71 substitution has diminished activity with a number of substrates, including CDNB and 7-chloro-4-nitrobenz-2-oxa-1,3-diazole. The low activity results from a significant increase in the K_m for GSH. Interestingly, there was no difference in the variant enzyme's specific activity toward Δ^5 -androstene-3,17-dione and no difference in the K_m for GSH with this substrate. Additional studies revealed that the L71 variant has diminished heat stability.

17.6.1.4 *GSTA4*. Thus far no SNPs in the coding region of *GSTA4* have been validated and characterized. Several SNPs have been identified in the 5' noncoding region, but they do not appear to influence function [131].

17.6.1.5 *GSTA5*. Thus far no SNPs in the coding region of *GSTA5* have been validated and characterized.

17.6.2 The Mu Class

Polymorphisms in the Mu class GSTs have been previously reviewed by Tetlow *et al.* [117]. Because of the similarity of some of the Mu class GST gene sequences, there are a number of alignment errors in SNP databases and the number of real coding region missense SNPs is less than that predicted. For example, there is an erroneous identification of an S210T substitution in both GSTM1 and GSTM2. This has arisen as a result of the misclassification of GSTM1 sequences with S210 and GSTM2 sequences with T210 and vice versa.

17.6.2.1 *GSTM1*. GSTM1 deficiency is the one most extensively studied GST polymorphisms. This polymorphism was first identified as a genetically determined GST deficiency with a frequency approaching 50% by starch gel electrophoresis [47]. At the same time, ion exchange chromatographic studies on human liver also revealed the absence of a significant GST isoenzyme in some samples [137]. Subsequent research also reported the inability of monocytes from some individuals to conjugate *trans*-stilbene oxide to GSH and this proved to be a result of GSTM1 deficiency since *trans*-stilbene oxide is a specific substrate for GSTM1-1 [138,139]. The original starch gel electrophoretic analysis predicted that GSTM1-1 deficiency was the result of a gene deletion and this was confirmed later by Southern blotting studies [83]. The *GSTM1* null allele is very common and is the most frequent allele in most populations studied so far. An association between GSTM1 deficiency and lung cancer was first reported in a study that was the forerunner of hundreds of investigations into the occurrence of GSTM1 deficiency and a range of different cancers and other disorders [140]. There have been a number of reviews and meta-analyses of these studies [141–152]. Possibly the most clinically significant studies have found that GSTM1 deficiency has a significant impact on survival of childhood leukemia [153–157].

The *GSTM1* null allele appears to have resulted from an unequal crossing over event that deleted an 18-kb region that included the entire *GSTM1* gene [158]. A polymorphic duplication of *GSTM1* has been reported in the Saudi Arabian population [159]. This variation results in an increase in an individual's capacity to conjugate *t*-stilbene oxide and presumably other GSTM1-1 substrates. Another GSTM1 polymorphism also originally identified by starch gel electrophoresis [47] and subsequently shown to result from an N173K substitution where the K173 variant has been termed GSTM1*A and the N173 isoform has been termed GSTM1*B [160] (Table 17.2). Functional studies have indicated that this polymorphism does not significantly affect the activity with a range of substrates [161]. An A85S substitution with a minor allele frequency of 0.068 in Caucasian Americans has been reported [116]. This variant has not been extensively characterized but appears to be stable when expressed in COS-1 cells.

17.6.2.2 *GSTM2*. Despite extensive studies, no confirmed missense SNPs have been identified in *GSTM2*.

17.6.2.3 GSTM3. Two coding region missense SNPs have been described and characterized [117]. A G147W substitution has been identified as a rare variant in Chinese subjects and a V224I substitution is common in African, Asian, and European subjects. These coding region alleles can be combined into four possible haplotypes (GSTM3*A, G147, V224; GSTM3*C, G147, I224; GSTM3*D, W147, V224; GSTM3*E, W147, I224). The term GSTM3*B has previously been used to describe a deletion in intron 6 (see below). Functional analysis of recombinant enzymes indicates that the presence of I224 in the GSTM3*C haplotype corresponds with a threefold increase in the specific activity with CDNB as a substrate, a reduction in the K_m for GSH, and a large increase in the catalytic efficiency of the enzyme [117].

The term GSTM3*B has previously been used to describe a deletion in intron 6 [118]. GSTM3*B appears to be in linkage disequilibrium with GSTM1*A and it has been suggested that this linked haplotype may include an element that alters the expression of GSTM1 [118].

17.6.2.4 GSTM4. Although the SNP databases predict a large number of missense SNPs, none has been validated as they can be explained as misalignments of other GSTM sequences. A 5' proximal promoter SNP at nucleotide-79 has been reported to influence expression. The G allele has only 67% of the activity of the C allele [131]. It is not clear if this difference is relevant *in vivo*.

17.6.2.5 GSTM5. No validated SNPs have been characterized in the coding region. Several variant alleles contribute to six haplotypes that have been noted in the 5' proximal promoter but none has been associated with a significant change in expression [131].

17.6.3 The Pi Class

17.6.3.1 GSTP1. The Pi class is represented in humans by a single functional gene (*GSTP1*). Although the SNP database lists several missense SNPs, only two have been validated and extensively characterized. The Ile105Val and Ala114 Val substitutions were first identified in cDNA clones [96] and later identified as genomic variants [162] (Table 17.2).

GSTP1-1 has been extensively studied in relation to drug resistance [35], and the possibility that the common SNPs at codons 105 and 114 alter drug and xenobiotic metabolism and susceptibility to cancer and other diseases has been the subject of numerous investigations [163–167]. Several studies have noted differences in the activity of GSTP1-1 variants with the anticancer drugs thiotepa and chlorambucil [163,168–170]. Many epidemiological gene association studies have been reviewed elsewhere and have been the subject of extensive meta-analysis [142,143,171–173]. Because of their potential impact on drug metabolism and drug resistance, the catalytic functions of GSTP1 variants have been intensively investigated. Most attention has been focused on the I105V substitution since residue 105 contributes to the architecture of the hydrophobic substrate-binding site (H-site) [174]. GSTP1-1 is active with a range of carcinogenic diol epoxides derived from polycyclic aromatic hydrocarbons [175–179] and differences in the GSH conjugating activity of the V105 and I105 variants have been attributed to the volume of the residue in the H-site and its hydrophobicity. It has been suggested that differences in the catalytic activity of the I105 and

V105 variants toward carcinogenic diol epoxides may underlie the reported associations between these alleles and cancer susceptibility [176], although other reports have implicated other factors [179]. Although most studies have identified significant catalytic and stability differences between the I105 and V105 variants [175,176], there have been contradictory reports. For example, while Zimniak and colleagues [180] reported that the I105 variant was less stable than the V105 variant at 50°C, a separate study indicated that the I105 variant was the more stable at 45°C [181]. Both studies found that the heat stability was differentially affected by the presence of substrates so the extent of GSH binding may explain this discrepancy and suggests that intracellular conditions could differentially affect the stability of the two variant isoenzymes and this could be reflected in different *in vivo* capacities to conjugate certain xenobiotics and their metabolites. Similarly, Johansson *et al.* [181] noted significant structure activity differences that were substrate dependent. For example, with CDNB as a substrate, the I105V polymorphism has significant affect on K_m but not k_{cat} . In contrast, with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole or ethacrynic acid as substrates, the polymorphism affected both parameters. Clearly, further studies are required to fully understand the structure/substrate interactions that underlie the reported associations between *GSTP1* genotype, xenobiotic metabolism, and cancer susceptibility.

17.6.4 The Theta Class

In humans, there are two functional Theta class GST genes (*GSTT1* and *GSTT2*) located on chromosome 22q11 [102,105]. The locus is complicated because of the apparent duplication of *GSTT2* to generate a pseudogene (*GSTT2p*) that is transcribed [102].

17.6.4.1 *GSTT1*. Although several missense mutations have been predicted in the SNP databases, few have been well characterized. The *GSTT1**A and *GSTT1**B alleles result from a T104P substitution that is relatively rare in Scandinavian populations [122]. The insertion of proline in helix 4 appears to destabilize the protein to a level that was below immunological detection and causes GSTT1-1 deficiency [122]. A major resequencing study [116] identified 18 SNPs, including the substitutions D43N, T65M, and V169I as well as a single nucleotide deletion (G412) from exon 4. With the exception of the V169I substitution that occurred at a minor allele frequency of 0.126 in African Americans, the other variants occurred at a frequency of 0.001 or less. The nucleotide 412 deletion causes a frame shift and a premature stop codon and would be expected to cause a deficiency. When transfected into COS-1 cells, the D43N, T65M, and T104P substitutions caused low levels of immunoreactive protein expression [116]. Two other rare variants (D141N and E173K) reported in the NIEHS Environmental Genome Project database have been expressed in *Escherichia coli* and characterized [123]. Although the D141N substitution had little effect on activity with 1,2-epoxy-3-(*p*-nitrophenoxy)propane, ethylenediiodide, and 4-nitrobenzyl chloride, and appeared to have a normal thermal denaturation profile, it had low activity in an ethylene dibromide mutagenicity assay. In contrast, the E173K substitution caused significant instability and had no or low enzymatic activity.

A *GSTT1* null allele (*GSTT1**O) is common in most populations and results from a gene deletion [102,103,182]. Since it was shown that GSTT1-1 can activate dihalomethanes to mutagenic intermediates [183], there has been considerable interest

in determining if the presence or absence of GSTT1-1 influences susceptibility to cancer and other disorders [184]. Many of the studies have been the subject of review and meta-analysis [143,146–148,150,185,186]. In addition to the potential role of GSTT1-1 deficiency in cancer susceptibility, mismatches in the *GSTT1* genotype between organ donors and recipients are considered to be significant risk factors in transplant rejection and in autoimmune hepatitis [187,188].

17.6.4.2 *GSTT2*. Although several GSTT2 missense SNPs have been included in the SNP database, close examination reveals that most can be attributed to sequence differences between GSTT2 and *GSTT2p* (also termed *GSTT2b*), a transcribed pseudo-gene that has been disabled by splice site changes and inframe stop codons [102]. Only one relatively rare missense SNP causing a M139I substitution has been unambiguously identified [102]. This protein has not been functionally characterized, but molecular modeling suggested that the enzyme's function is unlikely to be modified. A relatively common deletion of *GSTT2b* has recently been identified [106]. This deletion appears to diminish the transcription of *GSTT2* and is in linkage disequilibrium with the polymorphic deletion of *GSTT1*. Several SNPs generating at least four observed haplotypes in the 5' proximal promoter have been reported [131]. Of these, a T-105 to C-nucleotide substitution appears to result in a significant decrease in expression, but it is not clear if this study was able to differentiate between *GSTT2* and *GSTT2p*.

17.6.5 The Sigma Class

The human Sigma class GST is also known as *hemopoietic prostaglandin D synthase* (HPGDS). No functional polymorphisms have been unequivocally identified in the coding sequence but two rare variants in intron 2 (IVS2 + 11A > C) and intron 3 (IVS3 + 13T > C) have been reported [125]. In a survey of asthmatic families, the intron-2 SNP was significantly transmitted to asthma-affected children [125].

17.6.6 The Zeta Class

17.6.6.1 *GSTZ1*. In humans, there is a single Zeta class GST gene (*GSTZ1*) and it is located at chromosome 14q24.3 [6,54]. GSTZ1-1 is also known as *maleylacetoacetate isomerase* and catalyzes the penultimate step in the degradation of tyrosine [7]. Although deficiencies of other enzymes in this pathway are known and cause disease of varying severity, no cases of GSTZ1-1 deficiency have been unequivocally identified. Several missense SNPs have been identified that result in L8P, K32E, G42R, and T82M substitutions [124,189]. So far five haplotypes have been identified in human population studies (Table 17.2), and characterization of recombinant proteins has revealed a number of significant functional differences [124,189,190]. Notably, the GSTZ1*A haplotype generates a protein with a G42R substitution that has high specific activity with the (R)-enantiomer of 2-chloropropanoic acid and lower specific activity with the (S)-enantiomer. In contrast, the products of the other haplotypes showed no enantiomer selectivity. In addition, the GSTZ1*A protein has low isomerase activity with maleylacetoacetate and is resistant to inactivation by dichloroacetic acid (DCA) compared to the other GSTZ1-1 variants [124,190,191]. The impact of the arginine substitution at codon-42 on the active site and the functional properties of GSTZ1a-1a have previously been discussed in detail [190]. The resistance of the GSTZ1a-1a variant to inactivation

by DCA may be of clinical significance since DCA has been used to treat lactic acidosis [192] and has recently been proposed as a novel anticancer agent [193–195]. The pharmacokinetics of DCA disposition is complex. Although the elimination of DCA is dependent on the activity of GSTZ1-1, DCA also acts as a mechanism-based inactivator of GSTZ1-1 [191,196]. Consequently, the resistance of the GSTZ1a-1a variant to inactivation is likely to shorten the half-life of DCA in individuals with this allele. A cDNA clone with a L8P substitution has been identified in an EST database and although this allele was not identified in a study of 101 Europeans [124], it may be present in other ethnic groups.

A total of 10 SNPs have been identified in a region extending 1.5 kb upstream of the GSTZ1 start of transcription in African and European subjects [197]. Of these SNPs, only two (–1002G >A and –289C >T) were associated with significant changes in promoter activity. Further studies are required to determine if SNPs influence *GSTZ1* expression *in vivo*.

17.6.7 The Omega Class

In humans, there are two functional Omega class GST genes (*GSTO1* and *GSTO2*) that are located on chromosome 10q24.3 and are separated by about 1.5 kb [13,108]. A review of the structure and function of the Omega class GSTs has previously been published [107].

17.6.7.1 *GSTO1*. Several studies have reported missense SNPs or deletions in *GSTO1*, including C32Y, A140D, delE155, E208K, and A236V (Table 17.2) [108,126,198,199].

The C32Y substitution is a rare variant reported in Caucasians which is reported to degrade rapidly and has a short intracellular half-life [126]. As C32 is the primary active site residue [12], this substitution might be expected to eliminate the thioltransferase, methylarsonate reductase, and phenacylglutathione reductase activities of GSTO1-1. However, it might be expected to improve the enzyme's capacity to conjugate GSH to compounds such as CDNB since an experimental C32A substitution has been reported to increase activity with CDNB [107]. This activity may be further enhanced because of the substitution to tyrosine which is the active site residue in the Alpha, Mu, and Pi class GSTs that have very high GSH conjugating activity with CDNB.

The A140D substitution is the most common missense polymorphism at this locus. This substitution does not appear to have a significant effect on activity with a range of substrates [13,200].

The deletion of E155 occurs at a low frequency in most populations that have been studied and results from the deletion of AGG from the 5' splice donor site of exon 4 and the recreation of a new functional splice donor site (AGGAG/GT to AG/GT) [108,201]. Recombinant protein produced in *E. coli* has increased specific activity with several substrates [13] but low heat stability [108]. Recent data suggest that protein with the E155 deletion may be unstable *in vivo* and the allele could result in GSTO1-1 deficiency in homozygotes. This conclusion is based on the observations that the T47-D breast cancer cell line is hemizygous for the delE155 allele and is devoid of GSTO1-1 protein and activity [201]. In addition, transformed lymphoblastoid cell lines from delE155 heterozygous subjects show only 50% of normal GSTO1-1 enzymatic activity [201]. Given the low frequency of the delE155 allele in Europeans, it is expected

that homozygotes would be rare. However, the frequency of the deletion is more common in Chinese and one apparent homozygote was noted in a small sample of normal Chinese subjects, suggesting that the expected deficiency of GSTO1-1 is not particularly deleterious [108]. The delE155 allele is in strong linkage disequilibrium with an E208K substitution. In Europeans, the delE155 allele is linked to the K208 allele in contrast to Chinese subjects where the delE155 allele is linked to E208 [13]. Studies on recombinant GSTO1-1 with a single E208K substitution without the E155 deletion indicate that this mutation does not significantly affect the enzyme's stability or catalytic activity [13].

An A236V substitution has been reported in population samples from Chile and Mexico [126,127]. Evaluation of the recombinant protein has shown that the A236V substitution causes a marked decrease in the specific activity with all substrates tested and a significant reduction in heat stability [127]. It is likely that this substitution would lead to a deficiency of GSTO1-1 in homozygotes but none has been identified or studied so far.

Linkage disequilibrium has been reported within the *GSTO1* gene and between *GSTO1* and *GSTO2* [126]. Linkage studies have also shown that *GSTO1* modifies the age at onset of Alzheimer's and Parkinson's diseases [202,203]. This association has not always been evident in smaller studies [204,205]. GSTO1 polymorphisms have also been associated with vascular dementia and stroke [206,207]. The mechanisms underlying these associations with neurological disease are not clear, but as GSTO1-1 has been implicated in the activation of the proinflammatory interleukin-1 (IL-1) β [208] and as there are numerous reports of IL-1 variants influencing risk of Alzheimer's and Parkinson's diseases, this may be a profitable area for further investigation [209–212].

17.6.7.2 GSTO2. GSTO2-2 is difficult to express in heterologous systems and has not been extensively characterized. The limited studies that have been undertaken have shown that it has very high dehydroascorbate reductase activity [13]. With 66 polymorphisms being detected so far, the GSTO2 locus appears to be very polymorphic [126]. While most variation is in the noncoding regions, four missense SNPs have been characterized (V41I, C130Y, N142D, and L158I) [13,108,126]. The N142D substitution is the most common and is found in all populations studied so far. This substitution does not appear to influence catalytic activity [13] or stability [126]. Similarly, the V41I mutation appears to be relatively stable, but its catalytic activity has not been assessed [126]. In contrast, the C130Y and L158I substitutions are rare and appear to be relatively unstable [126].

17.7 STRUCTURE AND FUNCTION OF THE CYTOSOLIC GLUTATHIONE TRANSFERASES

17.7.1 Crystal Structures

Crystal structures have been determined for representatives of the known mammalian GSTs and many animal, plant, and microbial GSTs. Protein Database (PDB) files for representatives of all the human GST classes and the related CLIC proteins are provided in Table 17.3. Modeling has shown that the human GDAP1 may be a member of the GST structural family, but a definitive crystal structure has not been reported [57]. All

^aThese are representative structures and many additional structures with a variety of ligands are available in the PDB.

^bGSTS1-1 is also commonly known as *hemopoietic prostaglandin D₂ synthase* (HPGDS).

the catalytically active members of the GST family form dimers. While most GSTs form homodimers, there is some evidence that closely related subunits from within a class can form heterodimers. Heterodimerization is particularly evident between GSTA1 and GSTA2 subunits [77] and has been reported to occur between GSTM1 and GSTM2 subunits [213] *in vivo*, dimerization generally occurs within a class as the differences in structure of the dimer interface seems to limit the formation of interclass dimers. However, there is evidence for the formation of Pi–Mu heterodimers *in vitro* under mild nondenaturing conditions, suggesting that heterodimerization may occur *in vivo* in some circumstances [214]. Within the Alpha, Mu, and Pi classes and to a variable extent in other GSTs, the dimers are stabilized by “key and lock” interactions where a Phe or Tyr residue from one subunit is wedged into a hydrophobic pocket in the other subunit. There is evidence that at least in the Pi class, this stabilization indirectly affects the catalytic competence of the enzyme by stabilizing the loop following α -helix 2 that forms the GSH-binding “G”-site [215]. In this light, it is of interest that the Pi–Mu heterodimers reported by Pettigrew and Colman [214] displayed novel catalytic activity.

In vivo, members of the Pi and Mu classes can also occur in a monomer–homodimer equilibrium where the GST Pi or Mu monomers interact with other proteins such as JNK, ASK1, and Prx IV (peroxyredoxin IV) [14,15,226]. The binding of GST monomers to signaling proteins such as JNK and ASK1 highlight some novel noncatalytic roles for the cytosolic GSTs. The CLIC proteins are members of the cytosolic GST family that occur as monomers [18,20,21]. Although these proteins have no known catalytic activity, they can enter membranes and form ion channels [19,21,227,228].

Other studies have shown that they can modulate the activity of ryanodine receptor Ca^{2+} channels that are essential for muscle excitation–contraction coupling [18,229].

The archetypical “cytosolic” GST fold is composed of two domains (Figs. 17.1 and 17.2) [12,67,174,216,222,230]. The N-terminal domain that includes the GSH-binding site appears to have evolved from a thioredoxin/glutaredoxin ancestor and has a typical thioredoxin topology ($\beta\alpha\beta\alpha\beta\alpha$). The C-terminal domain is composed of a helical bundle that does not appear to have any clear evolutionary progenitor. In contrast, the mitochondrial GSTK1-1 appears to have arisen via a parallel evolutionary pathway, and although it manifests a thioredoxin-like fold, the $\beta\alpha\beta\alpha_n\beta\beta\alpha$ topology, differs significantly as the helical bundle is inserted between $\beta 2$ and $\beta 3$ [41,43]. This topology is shared with the bacterial disulfide bond-forming proteins (DsbA).

17.7.2 The Active Site and Catalysis

The active site can be subdivided into the “G”-site or GSH-binding site and the “H”-site that binds the hydrophobic substrate. The G-site primarily involves residues in the N-terminal domain (Fig. 17.2), but in some GSTs, the G-site can also involve residues from the second subunit [216]. The residues involved in binding GSH are generally well conserved across those GSTs that have enzymatic activity. In GSTs from the Alpha, Mu, and Pi classes, the G-site is relatively open and accessible. This has allowed the purification of these isoenzymes by GSH affinity chromatography [50,51]. In the Theta and Zeta classes, the G-site is more buried and this precluded their purification by affinity chromatography and delayed their discovery and characterization. In contrast to the G-site, the residues constituting the H-site are largely within the C-terminal domain (Fig. 17.2) and are variable across the GST structural family reflecting the diversity of the hydrophobic compounds that are substrates for the different isoenzymes. The primary active site residue responsible for catalysis is a tyrosine in the Alpha, Mu, Pi, and Sigma classes, a serine residue in the Theta and Zeta classes and a cysteine in

Figure 17.2 Two views of the crystal structure of a human cytosolic glutathione transferase GSTZ1 subunit (PDB code 1fw1) [67]. The N-terminal thioredoxin domain is shown in black, and the C-terminal helical domain is shown in gray. Glutathione, a sulfate ion, and dithiothreitol are represented in CPK stick format. The glutathione is in primary contact with N-terminal domain residues, and its thiol is positioned in the active site at the N-terminal of α -helix 1. The sulfate ion is coordinated by residues in the C-terminal domain and mimics the position of the second substrate. The dithiothreitol molecule forms a disulfide bond with Cys 205. (See color insert.)

the Omega class [12,67,107,216,222,231–233]. Tyr8 of human GSTA1-1 is conserved within the Alpha, Mu, Pi, and Sigma classes and its phenolic hydroxyl group is within hydrogen bonding distance of the GSH thiol. Mutation of Tyr8 to Phe caused a 90% loss of activity but was not absolutely essential for activity [216,231]. Subsequent mutation of Arg15 has confirmed that it also plays an important role in binding and activating GSH in the Alpha class where it is strongly conserved [234]. A conserved Ser residue appears to be important for catalysis in the Theta class GSTs; however, its precise role may vary with different substrates. Mutation of Ser11 in GSTT2-2 abolished its GSH peroxidase activity with cumene hydroperoxide and its GSH conjugating activity with ethacrynic acid but doubled its activity with 1-menaphthyl sulfate [232]. The Zeta class GST GSTZ1-1 is also known as *maleylacetoacetate isomerase* and undertakes the GSH-dependent isomerization of maleylacetoacetate to fumarylacetoacetate, the second last step in the catabolism of tyrosine. In addition, GSTZ1-1 catalyzes the GSH-dependent dehalogenation and oxygenation of α -haloacids such as DCA [190]. There are two adjacent serine residues and a cysteine residue (S₁₄, S₁₅, and C₁₆) in a highly conserved motif in the G-site of all Zeta class GSTs. Mutagenesis of these residues in human GSTZ1-1 found that only Ser14 is specifically required for catalysis despite its less favorable orientation toward the GSH thiol in the crystal structure [67,233]. The Cys16 residue is not essential for activity but does play a role in GSH affinity and binding [235].

The Omega class GSTs catalyze a range of reduction or thioltransferase reactions where cysteine could be expected to play a catalytic role. The determination of the crystal structure of GSTO1-1 shows GSH linked though a disulfide bond to Cys32 in the G-site and mutagenic studies confirmed that the thioltransferase and reductase activities are dependent on Cys32 [12,108,200]. Although GSTO1-1 does not normally catalyze conjugation reactions, mutation of Cys32 to Ala eliminates the thioltransferase and *S*-phenacylglutathione reductase activities but notably generates a novel GSH conjugation activity with CDNB [107].

The substitution reaction catalyzed by many GSTs has been well described [27,30] and is shown in the following equation:

The reaction proceeds from the initial lowering of the pK_a of GSH from around pH 9 in solution to around pH 6.5 when it is bound in the G-site. This promotes the deprotonation of the thiol to a highly nucleophilic thiolate anion. While some evidence suggests that the active site tyrosine and serine residues act as hydrogen bond donors that stabilize the GSH thiolate [30,234,236], there is additional evidence that the glutamyl α -carboxyl group of the bound GSH may accept the proton from the thiol group. The use of a decarboxylated analogue of GSH (4-aminobutyric-Cys-Gly) as a substrate for GSTA1-1 supported this proposal as the pK_a of the thiol increased from 6.7 to 9.2 and severely diminished the catalytic activity of the enzyme [237]. In addition, it has also been suggested that water molecules detected in the active site of some GST crystal structures could mediate the proton release [238,239]. A new model for GSH activation in GSTA1-1 has recently been proposed on the basis of QM/MM calculations. In this mechanism, an initial conformational change allows a water molecule to act as a bridge to assist in the transfer of the proton from the GSH thiol to the glutamyl α -carboxylate group [240,241]. Although this mechanism relies

on a conformational change that may be specific for the Alpha class GSTs, the original studies with 4-aminobutyric-Cys-Gly showing the absolute requirement of the glutamyl α -carboxylate for catalysis obtained similar results with rat Alpha, Mu, and Pi class GSTs suggesting that the mechanism is not restricted to the Alpha class [242,243].

17.8 GST-DEFICIENT MICE

The physiological role of GSTs and their contribution to the disposition of drugs and carcinogens is increasingly being studied in GST knockout mice and has been recently reviewed [244]. A list of the knockout mice strains and experimental studies is provided in Table 17.4. Although these mice can provide novel insights into drug metabolism, care should be exercised in the interpretation of the data in relation to its relevance in humans as not all human GSTs have exact equivalents in mice [244]. For example, mouse GSTA3-3 has high activity with aflatoxin B1 and protects mice against aflatoxin carcinogenesis [71,245]. In contrast, human GSTA3-3 has low activity with aflatoxin but exhibits a significant steroid hormone isomerase activity that is not present in the mouse enzyme [5]. Inactivation of the *GstA3* gene in mice eliminates their natural resistance to aflatoxin and provides a novel model of human aflatoxin susceptibility [245]. In other cases, such as the Pi and Theta classes, where there are different numbers of isoenzymes in humans and in mice, and because of some redundancy in specificity, elimination of a single isoenzyme may not create an appropriate deficiency model.

18.1 SUMMARY

Compared to most xenobiotic-metabolizing enzymes, knowledge of amino acid conjugation in terms of enzyme multiplicity, protein structure, and xenobiotic substrate selectivity is less advanced. Amino acid conjugation is a novel biotransformation pathway in man for a number of xenobiotic carboxylic acids, including arylacetic, aryloxyacetic, aromatic, and heteroaromatic acids. A notable example is salicylurate formation, which accounts for up to 85% of total salicylic acid clearance in humans.

Amino acid conjugation of xenobiotics involves two enzymatic processes that are localized in mitochondria. First, formation of a reactive xenobiotic–CoA thioester intermediate, catalyzed by an ATP-dependent acid:CoA synthetase (ACSM), and second, linkage of the activated acyl group via an acyl-CoA:amino acid *N*-acyltransferase (GLYAT) to the amino group of the acceptor amino acid. In humans, the principal amino acid utilized is glycine. Formation of a xenobiotic acyl-CoA thioester is an obligatory step in the overall process of amino acid conjugation. However, it is apparent that there are many more xenobiotics that form acyl-CoA thioesters than there are xenobiotics that are substrates for sequential metabolism by ACSM and GLYAT.

Although the active sites of the ACSMs and GLYATs clearly differ, detailed understanding of the metabolism of xenobiotic carboxylic acids via amino acid conjugation awaits the in-depth structural characterization of both proteins.

18.2 INTRODUCTION

The early pioneering work of Alexander Ure in 1841 laid the foundation for the field of amino acid conjugation by demonstrating that exogenously administered benzoic acid was metabolized to hippuric acid [1]. It was not until Dessaignes in 1845 determined that hippuric acid was a benzoic acid linked to glycine (benzoylglycine) that the first evidence of both a conjugation reaction per se and an amino acid conjugation reaction in humans was provided [2]. The future of the field seemed assured following the recognition that amino acid conjugation is the predominant route of metabolism of salicylic acid, with salicylurate (the glycine conjugate) formation accounting for 68–85% of the excretion of salicylic acid in urine. Although knowledge of conjugation reactions involving glucuronic acid, sulfate, and glutathione has advanced significantly, in relative terms, amino acid conjugation remains poorly understood and is limited to a number of arylacetic, aryloxyacetic, aromatic, and heteroaromatic acids.

For the majority of xenobiotic carboxylic acids, amino acid conjugation is a novel but minor metabolic pathway. However, rather than assignation in terms of importance to the bottom of the drug metabolism, enzymology ladder amino acid conjugation (or lack thereof) could be viewed as an evolutionary piece de resistance. Instead of exhibiting the substrate promiscuity of the cytochrome P450s (CYPs) or UDP-glucuronosyltransferases (UGTs), the relative substrate selectivity of the enzymes of amino acid conjugation has been very stable. This stability implies that the enzymes have a central role in the connectivity of biotransformation reactions, and hence, any disruption may have the potential to influence multiple pathways crucial to cellular integrity.

18.3 MECHANISM OF AMINO ACID CONJUGATION

A limited number of carboxylic acids are conjugated with an amino acid (principally glycine) before excretion. These include endogenous molecules (e.g., bile acids, branched chain fatty acids), environmental chemicals (e.g., herbicides), food preservatives (e.g., substituted benzoates), and drugs (e.g., salicylic acid and valproic acid (VPA)). In general, bile acid conjugation forming glycine and taurine conjugates is catalyzed by extramitochondrial (microsomal and peroxisomal) enzymes, while xenobiotic amino acid conjugation is mediated by mitochondrial enzymes. The latter is the focus of this chapter, and while much of our knowledge of amino acid conjugation both *in vivo* and *in vitro* is based on glycine as the acceptor amino acid, other amino acids are utilized in both man and other species. These include glutamine, glutamate, and taurine in man [3–5]; ornithine in birds and reptiles; and glutamine in ferrets, rabbits, and rats [6]. Formation of amino acid conjugates increases solubility and facilitates xenobiotic excretion in bile or urine.

In contrast to other conjugation reactions, amino acid conjugation is a coupled two-enzyme system. The general consensus is that amino acid conjugation proceeds through

- initial activation of the carboxylic acid moiety with ATP, generating an acyl adenylate and pyrophosphate;
- the reaction of the bound acyl adenylate with coenzyme A (CoASH) catalyzed by an ATP-dependent acid:CoA synthetase (AMP forming) to yield a “high energy” xenobiotic–CoA thioester intermediate;
- linkage of the activated acyl group via the action of an acyl-CoA:amino acid *N*-acyltransferase to the amino group of the acceptor amino acid with regeneration of CoASH (Fig. 18.1).

The formation of an acyl adenylate has not been proven unequivocally. However, multiple studies using proteins from liver and kidney of multiple species with an array of substrates indicate that the reaction follows a bi uni uni bi ping-pong mechanism. For example, using benzoate as the substrate, ATP binds first to the enzyme, followed in order by benzoate binding, pyrophosphate release, CoA binding, benzoyl-CoA release, and AMP release [7].

It is important to recognize at this stage that as a coupled enzyme reaction, a xenobiotic is first a substrate for the acid:CoA synthetase and then the xenobiotic–CoA conjugate is a substrate for the acyl-CoA:amino acid *N*-acyltransferase. Thus, specificity or selectivity of this metabolic route can be conferred at the level of either one or both enzymes. Furthermore, lack of amino acid conjugation does not necessarily infer lack of xenobiotic–CoA conjugation.

18.4 MITOCHONDRIAL MEDIUM CHAIN ACYL-CoA SYNTHETASES (ACSM)

An understanding of amino acid conjugation is predicated on the knowledge of the process of fatty acid activation and the commonality of the enzymes involved. Short-, medium-, and long-chain and very-long-chain fatty acids are activated to their corresponding acyl-CoA thioesters by different families of acyl-CoA synthetases (ACS). Since the fatty acid carbon chain length defines the selectivity of the different enzymes, the ACS superfamily has been subdivided into multiple subfamilies on the basis of fatty acid substrate selectivity. In biochemical terms, these enzymes were previously referred

Figure 18.1 Salicylurate formation. (a) Formation of acyl adenylate, (b) formation of salicyl-CoA catalyzed by medium chain acyl-CoA synthetase, and (c) conjugation with glycine to form salicylurate catalyzed by acyl-CoA:glycine *N*-acyltransferase.

to as *ligases* because of their role in “ligating” a fatty acid to CoA. However, in view of the diversity of substrates utilized, both endogenous and exogenous, synthetase was adopted to describe the activity of the enzymes and acyl-CoA for the product [8]. The approved root symbol is ACS followed by a letter that specifies the carbon chain length of the fatty acid substrates, for example, S, short; M, medium; and L, long. The ACS nomenclature was introduced in 2004 for the medium chain ACS (ACSM) subfamily.

Short-chain fatty acids (C_2 – C_4) are primarily activated by the cytosolic short-chain ACSs, and these enzymes are not considered to contribute to xenobiotic metabolism. Long-chain fatty acids (C_{12} – C_{20}) are activated by members of the ACSL family and are present in the outer mitochondrial membrane, endoplasmic reticulum (ER), and peroxisomes. The microsomal ACSL catalyze formation of the CoA thioesters of nafenopin, clofibrate, and the R(-)enantiomers of the 2-arylpropionic acid non-steroidal anti-inflammatory drugs [9,10]. In general, the xenobiotic–CoA thioesters formed in the ER are not substrates for the mitochondrial acyl-CoA:amino acid *N*-acyltransferases. Likely explanations include the fact that xenobiotic–CoAs do not cross biological membranes readily, and they may also be poor substrates for the carnitine shuttle.

The most important enzymes in terms of amino acid conjugation are the medium chain ACSs (ACSM). The ACSMs are located in the mitochondrial matrix and activate C_4 – C_{12} fatty acids. These medium chain fatty acyl-CoA esters are then utilized either for β -oxidation or in anabolic pathways for the formation of cellular lipids. The commonality of involvement of ACSM in both activation of fatty acids and xenobiotics suggests that intramitochondrial formation of a xenobiotic–CoA has the potential to perturb mitochondrial function.

A purified beef liver mitochondrial enzyme (“Mahler’s enzyme”) was first described to catalyze CoA conjugation of C_4 – C_{13} fatty acids and their oxidized derivatives, benzoic acid, phenylacetic acid, and 2,4-dichlorophenoxyacetic acid (2,4-D) [11]. Subsequent studies, however, determined that salicylic acid and *p*-aminosalicylic acid were not substrates for “Mahler’s enzyme,” and mitochondrial “salicyl-CoA” and “propionyl-CoA” ligases were isolated from bovine and guinea pig liver, respectively [12–14]. For the next 20 years, progress was slow because of persistent methodological problems with lability of the mitochondrial ACS and hydrolysis of the xenobiotic–CoA conjugates from contaminating acyl-CoA hydrolases. In 1995, Vessey and Hu used column chromatography to purify three mitochondrial medium chain ACSs from bovine liver [15]. The three forms were designated XL-I, XL-II, and XL-III, and their apparent molecular masses were 54.7, 55.6, and 52.5 kDa, respectively. Partial sequencing of purified XL-I revealed regions of high homology with the essential hypertension SA protein, suggesting a role for the metabolism of endogenous carboxylic acids in the regulation of blood pressure [16]. Subsequent screening of a bovine cDNA library with oligonucleotide probes complementary to short sequences of the N-terminus of XL-I or XL-III resulted in the isolation of a 2065-bp cDNA encoding a protein of 577 amino acids (molecular mass, 64 kDa, XL-III) and an incomplete (75%) cDNA encoding XL-I. Comparison of the amino acid sequence of XL-III and the partial sequence of XL-I revealed an overall identity of 60%, suggesting a common ancestral gene [17]. A fourth bovine liver mitochondrial medium chain ACS (molecular mass, 65.5 kDa) was purified in 1996 by Kasuya *et al.* [18] and for convenience has been termed XL-IV in this chapter.

Additionally, ACSMs have been purified from mouse kidney [19] and mouse liver mitochondria [20]. In a comparative study, Kasuya *et al.* established that there was 48.0% amino acid identity among the mitochondrial ACSMs of mouse, rat, and bovine liver [20]. Furthermore, they reported that the mouse butyryl-CoA synthetase (SA protein) shared 74.2% amino acid identity with bovine XL-III. The latter is identical to a lipoate-activating enzyme that was purified from bovine liver mitochondria [21].

Two human liver mitochondrial xenobiotic/medium chain fatty acid ACSs kinetically distinct from the corresponding bovine liver XL forms were isolated in 1999: HXM-A (now designated ACSM2B) and HXM-B [22]. Subsequent cloning of human liver cDNAs determined that HXM-A was a 64-kDa protein exhibiting 56.2%, 58.7%, and 81.5% amino acid identity to MACS1, XL-III, and XL-I, respectively [23]. The recombinant protein (expressed in COS-7 cells) had greater activity toward benzoic acid than phenylacetic acid, which was consistent with the substrate selectivity of the purified HXM-A protein [22]. In 2001, Fujino *et al.* [24] characterized two medium chain ACSs (MACS1, now ACSM1; and SA, now ACSM3) located on human chromosome 16p. Both the proteins were localized to the mitochondrial matrix, and MACS1 appears to be the same as HXM-B.

18.4.1 Xenobiotic Substrates of ACSM

It is not surprising, given the high amino acid sequence identity between the mitochondrial ACSMs, that there is considerable overlap in terms of fatty acid and xenobiotic substrates. Tables 18.1 and 18.2 provide an overview of the *in vitro* substrate profiles of purified or recombinant bovine and murine (Table 18.1) and human (Table 18.2) ACSM proteins. It is difficult to compare both the substrate selectivity and relative enzyme activity of the ACSMs because the range of substrates varies between different studies, and different protein sources and preparations have been used. Although relative activities with each substrate vary enormously, common substrates for all bovine XL enzymes and murine ACSMs include hexanoic acid, octanoic acid, benzoic acid, 4-chlorobenzoic acid, and VPA. Salicylic acid is metabolized by XL-I, XL-II, and XL-III, with respective apparent K_m values of 2.4, 2.2, and 2.5 μM and respective V_{max} values of 1.2, 1.4, and 0.24 nmol salicyl-CoA formed per minute milligram of protein [25]. However, negligible activity was observed with XL-IV [26]. From the data detailed in Table 18.1, 1-naphthylacetic acid and 3-phenoxybenzoic acid are not substrates for XL-I and XL-II but are substrates for XL-III, XL-IV, and the murine liver and kidney forms of ACSM [15,18–20,24–27].

In contrast to the bovine and murine proteins, the substrate profile of the human forms HXM-A and HXM-B is poorly characterized (Table 18.2). Of the limited number of fatty acids investigated, substrate selectivity (C_4 , C_6 , and C_{10}) is similar to the bovine and murine enzymes. The only xenobiotic investigated was salicylic acid; K_m^{app} values for salicyl-CoA formation by HXM-A and HXM-B were 7.4 and 25 μM , respectively [22]. Formation of salicyl-CoA in humans is thought to be the rate-limiting step in clearance of salicylic acid to salicylurate, the latter accounting for the majority of total salicylic acid clearance in humans [28]. Salicylic acid clearance is greater in males than females due largely to enhanced salicylurate formation, but oral contraceptive steroid (OCS) use negates the gender difference in salicylic acid disposition parameters between males and OCS users [29]. At therapeutic doses, salicylurate formation

is a saturable process, and this contributes to the dose-dependent nonlinear pharmacokinetics of salicylic acid [30,31]. Although the $V_{\max}$ value of the purified HXM-A protein was 0.7 nmol/min.mg [22], the catalytic efficiency calculated as k_{cat}/K_m is 0.006 $\mu\text{L}/\text{min.pmol}$ protein, suggesting that HXM-A is unlikely to be the sole enzyme responsible for salicyl-CoA conjugation *in vivo*.

In addition to the xenobiotics listed in Tables 18.1 and 18.2, mitochondrial ACSM catalyzes CoA conjugation of hypoglycin A [32], pivalate [33], 2-tetradecylglycidic acid (TDGA) [34], 3-mercaptopropionic acid [35], zomepirac [36], and 3-oxapentanoic and 3,6-dioxahexanoic acid, the carboxylic acid metabolites of the ethylene-glycol-based solvents 2-ethoxyethanol and diglyme, respectively [37].

18.4.2 Substrate Structure–Activity Relationships

As relatively few drugs and chemicals are activated to acyl-CoA thioesters, distinct physiochemical features of the xenobiotic presumably influence the initial conjugation reaction. Using a variety of aromatic and arylacetic acids and purified bovine liver ACSM, Kasuya *et al.* [18] observed high activity toward saturated straight medium chain fatty acids in contrast to aromatic acids. Investigation of benzoic acid derivatives showed that highest activity occurred with alkyl or alkoxyl substitutions in the para- or meta-position of the benzene ring, while ortho-substituted benzoic acids were not

activated to their corresponding acyl-CoA esters. Arylacetic acids, such as 1-naphthylacetic acid, exhibited similar activity to benzoic acid, while VPA, a branched medium chain fatty acid, exhibited negligible activity [18]. High activity (relative to hexanoyl-CoA formation) has also been observed for benzoic acids with methyl, methoxy, ethoxy, phenoxy, and *n*-pentyl and *n*-heptyl substituents [38].

Studies investigating the mechanism of valproyl-CoA toxicity found that α -fluorination of Δ^4 -VPA [39] and VPA [40] prevents the formation of the corresponding acyl-CoA derivative and, in the case of Δ^4 -VPA, prevents hepatic steatosis [39]. Similarly, lack of formation of acyl-CoA thioesters has been shown for α -fluoropalmitic acid, perfluorooctanoic acid, and perfluorodecanoic acid [41,42]. These data suggest that fluorine, an electron-withdrawing substituent, alters the molecular recognition by ACSM. As noted above, substitution of fluorine at the α -carbon in VPA prevents formation of Δ^4 -VPA acyl-CoA. This may be explained by the increased acidity of the carboxyl group due to the electronegativity of the fluorine atom (F-VPA, pK_a 3.55) in comparison to VPA (pK_a 4.80) [40]. Recently, a positive electron-deficient “patch” adjacent to the electron-withdrawing fluorine substituent has been identified on the electrostatic surface of Δ^4 -VPA [43]. This electrostatic feature of the fluorinated analog may account for the loss of molecular recognition by ACSM.

Recently, a crystal structure (3EQ6) of human ACSM2A with butyric acid bound in the active site has been reported [44], although full details of the structure appears not to have been published. Fifteen putative substrate-determining residues (SDRs) were identified: Phe-234, Asp-235, Ala-236, Trp-239, Thr-278, Ile-299, Ala-301, Gly-302, Ala-322, Tyr-323, Gly-324, Pro-325, Ile-330, Cys-331, and Lys-517. In addition to the 15 SDRs common to the ACS family of enzymes, an additional conserved histidine at position 210 was identified to be important in determining the chain length of medium chain fatty acid substrates, while disfavoring the binding of long-chain fatty acids [44]. Further site-directed mutagenesis studies are required to elucidate the importance of these residues in the binding of xenobiotics.

18.4.3 Inhibitors of ACSM

The bovine forms XL-I and XL-III show substrate-inhibition kinetics with salicylic acid, and although ibuprofen is a specific substrate for XL-III, it inhibits all three XL forms with K_i values in the range of 70–125 μ M [25]. Using a purified mouse liver ACSM and hexanoic acid as the substrate, Kasuya *et al.* demonstrated competitive inhibition by diflunisal (K_i 0.6 μ M), 2-hydroxynaphthoic acid (K_i 13.4 μ M), 2-hydroxydodecanoic acid (K_i 15 μ M), nalidixic acid (K_i 12.4 μ M), and salicylic acid (K_i 19.6 μ M) and mixed-type inhibition with enoxacin and ofloxacin with respective K_i values of 23.7 and 38.2 μ M [45]. Recently, it was demonstrated that while triacsin C is a potent inhibitor of ACSL ($K_i < 1 \mu$ M), this compound is a relatively weak inhibitor of HXM-A and HXM-B ($K_i > 100 \mu$ M) [46].

18.5 MITOCHONDRIAL ACYL-CoA:GLYCINE *N*-ACYLTRANSFERASE (GLYAT)

The second step in the overall process of amino acid conjugation in mammals most commonly involves transfer of the acyl group to the amino group of glycine. This

reaction is catalyzed by acyl-CoA:glycine *N*-acyltransferases (GLYAT, EC 2.3.1.13) located in the mitochondrial matrix. Kinetic studies with bovine GLYAT are consistent with a sequential bi–bi mechanism where the acyl-CoA substrate binds first, followed by addition of the amino acid, before dissociation of CoA, and the release of the peptide product as the final step [47]. GLYATs, which are principally found in the mitochondria of liver and kidney, differ from the bile acid:CoA amino acid *N*-acyltransferase (EC 2.3.1.65) that conjugates bile acids with either taurine or glycine. Following identification in beef liver mitochondria in 1953 [48], two glycine *N*-acyltransferases were purified from human liver mitochondria in 1976 [49] and 1994 [50]. One was specific for glycine and utilized either butyryl-CoA or benzoyl-CoA as acyl donors, while the second enzyme conjugated phenylacetyl-CoA or indoleacetyl-CoA with glutamine [49].

18.5.1 Xenobiotic Substrates of GLYAT

Specificity of the bovine liver GLYATs has been demonstrated. The “phenylacetyltransferase” protein exhibits activity toward phenylacetyl-CoA, phenoxyacetyl-CoA, and 2,4-D but not toward 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), while the “benzoyltransferase” protein conjugates both 2,4-D and 2,4,5-T [51]. However, both GLYATs exhibited very high K_m values for glycine (100 and 1000 mM) and slow catalytic rate constants with the phenoxyherbicide-CoAs [51].

Detailed *in vitro* studies of the substrate profile of human GLYAT are lacking. Mawal and Qureshi [50] reported K_m values of 58 and 84 mM for benzoyl-CoA and salicyl-CoA, respectively. In general, evidence of amino acid conjugation principally results from identification of conjugates in human urine (Table 18.3). Glycine conjugation has been observed for the histamine H_1 receptor antagonists astemizole [52] and brompheniramine [53], the insecticide permethrin [54], the antiplatelet agent triflusal [55], and the solvent *m*-xylene [56]. In contrast, a taurine conjugate of ibuprofen was identified in human urine [5].

18.5.2 Substrate Structure–Activity Relationships

Current data indicates that CoA thioesters, which are substrates for amino acid conjugation, exhibit varying affinities for GLYAT [57]. From studies of the reactivity of acyl-CoA thioesters with glutathione, a simple structure–activity relationship based on substitution of the carbon α to the acyl carbon and on the presence of an oxygen atom β to the acyl carbon has been proposed [58]. Clearly, structural aspects of the xenobiotic–CoAs influence reactivity, and this is most likely associated with the functionality adjacent to the carboxylic acid group. Although this is an interesting observation, it does not account for the selectivity of the GLYATs, and no studies to date have characterized the factors that determine the recognition of xenobiotic acyl-CoAs by GLYAT.

18.5.3 Glycine Conjugation *In Vivo*

Unlike the majority of metabolic pathways that follow first-order kinetics *in vivo*, glycine conjugation is readily saturable, and hence, metabolism of some carboxylic acids is dose dependent. Depending on the substrate, the rate-limiting step can be either formation of the acyl-CoA intermediate or acyl transfer of the amino acid. In

TABLE 18.3 Xenobiotics Metabolized via Amino Acid Conjugation as Either the Parent Acid or Carboxylic Acid Metabolite in Humans

Parent Compound	Carboxylic Acid Metabolite	Amino Acid Conjugate	References
Astemizole	4-Fluorobenzoic acid	2-[4-Fluorobenzoyl]amino]acetic acid ^a	50
	2-(4-Methoxyphenyl)acetic acid	2-[[2-(4-Methoxyphenyl)acetyl]amino]acetic acid	50
	2-(4-Hydroxyphenyl)acetic acid	2-[[2-(4-Hydroxyphenyl)acetyl]amino]acetic acid	50
Brompheniramine	3-(4-Bromophenyl)-3-pyridin-2-yl-propanoic acid	2-[[3-(4-Bromophenyl)-3-pyridin-2-yl-propanoyl]amino]acetic acid	51
Ibuprofen	NA	2-(2-[4-(2-Methylpropyl)phenyl]propanoylamino)ethanesulfonic acid	5
Permethrin	3-(2,2-Dichloroethenyl)-2,2-dimethyl-cyclopropane-1-carboxylic acid	2-[[3-(2,2-Dichloroethenyl)-2,2-dimethyl-cyclopropane carbonyl]amino]acetic acid	52

<i>m</i> -Xylene	NA	2-[3-Methylbenzoyl]amino]acetic acid	54

Formation of the respective acyl-CoA thioester conjugate has not been demonstrated.

Abbreviation: NA, not applicable.

^aBenzoylaminoacetic acid is commonly referred to as *hippuric acid*.

Source: Adapted from Knights *et al.* (2007) [43].

addition to the kinetic characterization of ACSM and GLYAT, the two other factors that could result in saturation are the availabilities of the cosubstrates, coenzyme A, and glycine. Indeed, conjugation of benzoic acid and salicylic acid *in vivo* is concentration dependent but the mechanism differs. Formation of hippuric acid from benzoic acid is limited by the availability of glycine [6], while in humans, formation of salicyl-CoA is the rate-limiting step in the amino acid conjugation of salicylic acid [6,29].

Administration of exogenous glycine to rats confirmed that hippuric acid formation was limited by the availability of glycine [59]. Increasing the availability of the hepatic pool of CoA following dietary feeding with fenofibrate or bezafibrate led to an increase (8- to 10-fold) in hepatic CoA concentration and no change in benzoyl-CoA synthetase activity but a decrease in GLYAT activity [60]. Despite an increase in the available pool of CoA, the effect of fibrates was so complex that no conclusive evidence could be provided that the availability of CoA influenced glycine-conjugating capacity.

In humans, glycine conjugation of salicylic acid is capacity limited at therapeutic doses; however, oral administration of glycine does not “unsaturate” salicylic acid conjugation, suggesting that glycine availability is not a limiting factor [31]. Further studies conducted in 1969 in humans identified that formation of hippuric acid following oral administration of benzoic acid was also capacity limited. Concomitant administration of glycine markedly increased the rate of formation of hippuric acid. In contrast, prior administration of salicylic acid (1–3 g) had no measurable effect on hippuric acid formation [61]. The same study confirmed that salicylurate formation was capacity limited and that glycine availability had no measurable effect. However, administration of benzoic acid inhibited salicylurate formation, an effect not ameliorated by coadministration of glycine [61]. These data support the proposition that the availability of glycine is rate limiting for hippuric acid formation but not for salicylurate formation, while acyl-CoA conjugation is the rate-limiting step for salicylic acid but not for benzoic acid.

18.5.4 Inhibitors of Amino Acid Conjugation

As indicated, benzoic acid inhibits the elimination of salicylurate in man [61]. Since the activation step is rate limiting for salicylic acid and both are common substrates for the same ACSM, it is reasonable to assume that benzoic acid will inhibit salicyl-CoA formation *in vivo*. Indeed, benzoic acid does inhibit salicylic acid activation by bovine ACSMs *in vitro* [25]. However, salicylic acid also inhibits benzoic acid conjugation *in vitro* [25], and yet, in man, it does not appear to affect the formation of hippuric acid *in vivo* [62]. Ethanol is another proposed inhibitor of amino acid conjugation. Although ethanol was found to have no effect on the elimination of hippuric acid, it inhibited benzoyl-CoA conjugation [62]. In contrast, ethanol had no effect on either salicyl-CoA formation or the excretion of salicylurate [62].

18.6 LIFE SPAN ASPECTS OF AMINO ACID CONJUGATION

Human newborns have limited capacity to excrete *p*-aminobenzoic acid as a glycine conjugate [63]. Consistent with this *in vivo* finding, human liver and kidney homogenates from newborns have limited capacity to form glycine conjugates of benzoic and *p*-aminobenzoic acid [64,65]. Not surprisingly, wide variability in

hippuric acid excretion is observed in neonates and infants administered benzoic acid for the treatment of hyperammonemia [66]. This may be explained in part by immaturity of GLYAT, which appears to attain peak activity at 18 months of age [67]. However, salicylurate formation is detectable in fetal human liver slices [64]. To date, developmental maturity of the human ACSMs has not been investigated.

The capacity for glycine conjugation appears to decline with advancing age, and *in vivo* formation of hippuric acid from benzoic acid is known to decrease in the elderly [68]. Using human tissue homogenates from individuals aged 23–86 years, it was demonstrated that the capacity of the liver (but not the kidney) to form hippuric acid decreased slightly with age [69].

18.7 CONCLUSIONS

With the exception of salicylic acid, amino acid conjugation is a relatively minor pathway of metabolism of carboxylic acid xenobiotics. The limited number of xenobiotics that have been identified to form amino acid conjugates may reflect poor sensitivity of metabolite assays and also limited recognition of this metabolic route in humans. However, manipulation of this pathway is used clinically in the treatment of nonketotic hyperglycinemia and hyperammonemia in neonates and infants [66,70,71]. Additionally, the serum concentration of *p*-aminohippuric acid has been investigated as a prognostic test in hepatic failure [72,73], and 2-[[3-(2,2-dichloroethenyl)-2,2-dimethylcyclopropane carbonyl]amino]acetic acid, the glycine conjugate of the pyrethroid insecticide permethrin, has been proposed as a urinary biomarker of human exposure [52]. These studies provide little in the way of mechanistic insight as availability of the cosubstrates, CoASH and glycine, and the substrate selectivity of ACSM and GLYAT can all impact the overall process of amino acid conjugation.

It is evident, however, that there are many more xenobiotics that form acyl-CoA thioesters, which are not substrates for amino acid conjugation, than there are xenobiotics that are substrates for both the ACSM and GLYAT. Limited data from structure–activity studies have alluded to the subtle nature of the active site of human ACSMs, but these studies have provided no information on factors influencing recognition of the xenobiotic acyl-CoA by GLYAT. Further elucidation of the critical structural aspects of substrates that confer amino acid conjugation and knowledge of the active sites of the enzymes involved, namely, ACSM and GLYAT, are essential for understanding the broader potential contribution of amino acid conjugation to xenobiotic disposition.

1.1 INTRODUCTION

Discovery and development of a new drug is a risky, a time-consuming, and an extremely expensive business. Recent studies revealed that it takes an average time of 12–14 years and costs more than one billion dollars to discover, develop, and approve a new drug in the United States. The advances in chemistry, high throughput screening, molecular and cell biology, and human genomics have resulted in a multi-fold increase in the number of new chemical entities (NCEs) for preclinical and clinical evaluations. The applications of parallel synthesis and combinatorial chemistry to expedite lead finding and lead optimization processes has shifted the chemical libraries toward poorer biopharmaceutical properties, that is, poor solubility and higher molecular weight (MW). It has been estimated that for every 5000 NCEs evaluated in a discovery program, only one is approved for market. At any point during the drug development process, a prospective drug may be terminated due to lack of *in vivo* efficacy, serious undesired side effects, and poor pharmacokinetic (PK) and absorption, distribution, metabolism, and excretion (ADME) properties. Therefore, efforts are being made to reduce attrition of drug candidates during the various stages of their development to bring safer compounds to market. The early refinement of these ADME properties has been regarded as an essential part of the drug candidate selection process.

In support of this need, and as a consequence of increased knowledge within the drug metabolism discipline, new approaches have been developed, which include extensive *in vitro* methods using human and animal hepatic cellular and subcellular systems, recombinant human drug-metabolizing enzymes (DMEs), transgenic animals and cell lines stably expressing human transporters, increased automation for higher throughput screens, sensitive analytical technologies, and *in silico* computational models to assess drug metabolism aspects of the NCEs [1–3].

The ideal drug candidate should be able to provide sustained exposure, undergo balance clearance pathways with multiple enzymes, and not interfere with DMEs and transporters. Therefore, the design of drugs with optimal potency, PK properties, and less toxicity is still challenging, given the opposing requirements for absorption and metabolism. In the past decade, multiple *in silico*, *in vitro*, and *in vivo* ADME tools have been developed and implemented in various stages of the drug discovery and development process to alert chemists of potential ADME issues in the clinic [1–3]. Although significant improvements have been made to reduce the failure rate due to human PK-related issues, the overall attrition rate has not been improved [4]. The reason for attrition has been shifted to efficacy and safety. However, the ineffective efficacy, safety, and PKs are all interrelated and assignment of failure to a distinct factor might be misleading. For example, the poor efficacy of a drug candidate might be due to extensive metabolism, and clearance to inactive metabolites arising from induction of DMEs and its toxicity might be due to formation of toxic metabolites and/or its prolonged and unnecessary exposure arising from inhibition of the DMEs and transporters. Therefore, quantitative prediction of human PK parameters still presents the single most difficult challenge in the design and advancement of drug candidates to the development stage. Nonetheless, it could be argued that high throughput ADME screens contribute to the selection of the right molecule with the best PK properties for success in humans [4]. The objectives of these screens are to optimize absorption, plasma clearance, metabolic stability, plasma protein binding (PPB), and ratio of metabolic to renal/biliary clearance and to minimize intestinal/hepatic first-pass metabolism, inhibition/induction of DMEs and transporters, metabolism by polymorphic DMEs, and the formation of reactive metabolites of the NCEs. In this chapter, we will attempt to discuss the various ADME profiling approaches in drug discovery and development process and the latest technologies of the selected assays.

1.2 WHAT IS ADME?

When a compound is administered intravenously, the dose is delivered directly into the systemic circulation. All other routes of administration are collectively termed *extravascular routes* (e.g., oral, parenteral, topical, rectal, buccal, and sublingual). For drugs, oral administration is the preferred dosing route due to convenience and to enhance patient compliance. Delivering a drug to its desired target receptor site after an oral dose involves several complex steps of ADME.

The “A” in ADME represents the absorption, the processes that involve transferring the drug from the gastrointestinal (GI) fluid across primarily the jejunum and the ileum segments of the small intestine into the portal blood system. Thus, a drug must pass through to one or more layers of membranes either by passive diffusion, facilitated passive diffusion, or active transport to reach the systemic circulation. Drug

has to cross epithelial or mucosal cell walls, endothelial or capillary cell walls (blood stream), and cellular plasma membranes to exert effect. The extent and rate of absorption are dependent on physicochemical properties, drug formulation, and anatomy and physiology of the site of absorption.

Solubility and permeability are the key determinants of a compound's absorption after its oral administration, and in ultimately determining "how much compound is available to the body," a term also called *oral bioavailability* (OBA). During development of a chemical series, it is very important to ensure that the series has optimal solubility and permeability to avoid inaccurate results not only in biochemical and cell-based *in vitro* biology assays, which are designed to assess compounds' potency to target biological receptors, but also in basic *in vitro* ADME assays, designed to optimize "drug-like" properties of a chemical series. Poor solubility and poor permeability are two major reasons for misinterpretation (or complete lack) of structure–activity relation (SAR) in chemical series as well as for a disconnect between biochemical and cellular assays. Lead optimization of poorly soluble and permeable compound, based on *in vitro* assay results, is extremely risky and can cause compound failure in later stages of the drug development, when a significant amount of resources have already been invested. A common guide that is routinely used by discovery teams to get an estimate of the desirable solubility and permeability for a chemical series is given by the maximum absorbable dose (MAD) [5]. MAD is a function of solubility and permeability and is shown in the following equation:

$$\text{Target solubility (mg/mL)} = \frac{0.015 \times \text{Target dose (mg)} (\text{MAD})}{\text{Permeability (min}^{-1})} \quad (1.1)$$

(assuming all the administered drug is completely absorbed, i.e., target dose = MAD).

In general, for a compound of average permeability and a projected clinical dose of 1 mg/kg, the aqueous solubility should be greater than 50–100 $\mu\text{g/mL}$ [6].

The "D" in ADME represents the distribution, that is, "the reversible transfer of a drug from one location to another within the body." The compound is distributed to different tissues of the body after entering into the systemic circulation (i.e., blood). In most cases, the volume of distribution at steady state (V_{dss}) is used to describe the distribution of a compound in the body. Distribution is generally uneven because of differences in blood perfusion, tissue binding, regional pH, and permeability of cell membranes. The distribution (which tissue and what rate?) of a drug is an important parameter in determining its pharmacological action. The acidic drugs such as warfarin and aspirin are highly protein bound and thus have a small apparent volume of distribution. The basic drugs (e.g., amphetamine and meperidine) are extensively taken up by tissues and thus have an apparent volume of distribution larger than the volume of the entire body.

The "M" in ADME represents the metabolism of a compound by enzymatic reactions. It is a biochemical process by which xenobiotics (e.g., drugs) are converted to more hydrophilic (water soluble) entities, which enhance their elimination from the body [7,8]. Metabolism occurs primarily in the liver and also can occur in other organs (e.g., lung, intestinal epithelial, and kidney). Drugs are metabolized in two different stages: phases I and II. Phase I, or functionalization, reactions include hydroxylation (aliphatic, aromatic, or nitrogen), epoxidation (aliphatic or aromatic), dealkylation (O–, N–, or S–), deamination, oxidation (N–or S–), reduction (nitro, disulfide, keto,

aldehyde, or olefin), and hydrolysis (amide, ester, carbamate, or epoxide). These reactions introduce or unmask a functional group (e.g., $-\text{OH}$, $-\text{CO}_2\text{H}$, $-\text{NH}_2$, or $-\text{SH}$) within a molecule to enhance its hydrophilicity. Phase II, or conjugation, biotransformations include glucuronidation, sulfation, methylation, acetylation, and amino acid (glycine, glutamic acid, and taurine) and glutathione (GSH) conjugation. Most phase II reactions result in a compound's concomitant increase in hydrophilicity and decrease in volume of distribution (V_{dss}), which together greatly facilitate its excretion from the body. The rate and extent of metabolism of a drug determines the dose of drug and the duration of drug effect.

The "E" in ADME represents the elimination (i.e., irreversible removal) of a compound by liver, kidney, and other organs from the body. After oral absorption, drugs are eliminated from the body via excretion as unchanged forms in urine and bile and/or metabolism followed by excretion. For a drug whose clearance is dependent on metabolism, its intrinsic metabolic stability dictates the unbound drug concentrations and the duration of pharmacological effects.

1.3 FACTOR AFFECTING ADME

1.3.1 Physicochemical Properties

Several physicochemical properties of chemical compounds are determinants of intestinal drug absorption, and Lipinski's rule-of-five is a good starter set of rules to predict good absorption [9]. The compounds with MW <500 , lipophilicity <5 (calculated $\log P$), total hydrogen bond acceptors <10 (acceptors being O and N), and total hydrogen bond donors <5 (donors being O-H and N-H groups) should have good oral absorption. It was proposed that when a compound violates two or more of these five rules, it will likely have poor intestinal absorption.

1.3.1.1 MW and Lipophilicity. One of the basic and simple parameters that affect a compound's absorption is its molecular size, which can be estimated fairly reasonably by its MW. Lower MW compounds generally have better absorption and lower biliary excretion. Another metric, the polar surface area (PSA), which reflects a compound's capacity to form H-bonds, is a critical determinant of permeability. It is proposed that compounds with $\text{PSA} > 140 \text{ \AA}^2$ will be absorbed $<10\%$ across the intestinal wall and hence possess poor bioavailability [10]. This relationship holds when compounds are primarily absorbed via a passive transcellular diffusion route and there is no involvement of active transporters.

Lipophilicity, commonly denoted as $\log P$, is defined as the ratio of the compound concentration between an organic phase and the aqueous phase at equilibrium. In general, a $\log P$ value of 0–3 is considered optimal for passive diffusion [11]. A $\log P$ value of <1 suggests that a compound will have good solubility by virtue of being hydrophilic but will have a poor permeability. Similarly, a $\log P$ value of >3 suggests that a compound is highly lipophilic and may possess low solubility or be prone to metabolism and/or biliary excretion.

1.3.1.2 Ionization Constant (pK_a). Ionization constant is a useful thermodynamic parameter to modulate the charge state and eventually solubility, permeability, and key

properties of an NCE. Therefore, accurate measurements of pK_a of an NCE allows for properly predicting and interpreting ADME properties. The ratio of the total drug, ionized plus unionized, in the aqueous medium and the organic phase is defined as the distribution coefficient, denoted as D and commonly reported as $\log D$ [11]. P (as in $\log P$) is a pH-independent parameter, while D is a pH-dependent parameter. In general, a $\log D_{7.4}$ value between -0.5 and 2 is considered optimal for oral absorption. Compounds with $\log D_{7.4}$ values <-0.5 have poor permeability, while those with $\log D_{7.4}$ values >2 are limited by poor solubility.

1.3.1.3 Solubility and Dissolution. Low solubility of NCEs remains a major drug development challenge since it not only causes aberrant results (artificially low potency) in *in vitro* cell assays [12] in the hit-to-lead stages but also can cause lack of efficacy in preclinical/animal models due to poor exposure, nonlinear PK, significant animal-to-animal PK variability, uncertainty in exposure prediction in humans, and formulation difficulties during clinical development. Significant time and revenues of research and development (R&D) are invested in developing a poorly soluble compound, via salt screens and formulation screens. Hence, it is highly desirable to avoid development of a poorly soluble compound from the early stages of drug development. Solubility is guided by two important parameters: lipophilicity and tightness of crystal structure, both of which are inversely related to solubility. Investigation of intrinsic solubility of poorly soluble marketed drugs revealed that several of these showed solvation-limited solubility (high lipophilicity), rather than solid-state-limited solubility (high energy of crystallization).

Several examples in the literature highlight medicinal chemistry efforts to improve solubility, via introduction of ionizable, N-containing basic groups [7,13,14], or disruption of planar crystal structure [15,16], as is shown in Fig. 1.1 for the selected literature examples.

Prodrug approaches have also been used to improve solubility of drugs such as that shown in Fig. 1.2. Fosamprenavir, a phosphate prodrug for the HIV protease inhibitor, amprenavir, showed a 10- to 1400-fold (in the pH range 3.3–7.4) improvement in solubility [17].

1.3.1.4 Permeability. Membrane permeability is not just critical for absorption across the biomembrane of the GI tract but also plays a very important role in its distribution to all other tissues of the body. Compounds can traverse the epithelial cell membranes via either (i) passive transcellular, (ii) passive paracellular, or (iii) active influx/efflux transporter-assisted routes. Majority of the neutral lipophilic drug candidates enter cells through the passive transcellular route, while hydrophilic or charged drugs do so via the passive paracellular route. Since the surface area of the tight junctions is about 0.01% of the small intestine surface area, the paracellular route of absorption is not a very efficient route as compared to the passive transcellular route, which takes place across the much larger surface area of the apical membrane of enterocytes' microvilli environment. Contribution of numerous transporters to drug uptake and efflux has also received a lot of attention in recent years.

Physicochemical properties of compounds alone sometimes fail to give insight into its permeability since there are various permeability pathways that involve specific transporters, which are essentially proteins that recognize the drugs in specific ways that cannot be predicted, based on physicochemical properties itself. In general, an increase

Figure 1.1 Literature examples of solubility optimization due to (a) introduction of ionizable groups and (b) disruption of crystal packing.

in lipophilicity, decrease in H-bonding, and reduction in polarity of a chemical series has been found to improve permeability of compounds [18–20] (Fig. 1.3). Sometimes, these changes do not always lead to an expected increase in the improvement of Caco-2 permeability as seen during structure optimization of a series of phenothiazine carboxylic compounds as novel histamine H₁ antagonist [21].

Attaining permeability of drug candidates across the blood–brain barrier (BBB) is a challenge in the development of central nervous system (CNS) drugs with only 2% of the CNS discovery compounds being able to cross the BBB to impart their therapeutic efficacy. Like Lipinski's rule-of-five, there are some predictive rules such as Clark's rule and Pardridge's rule, which are able to predict permeability across

Figure 1.2 Overcoming poor solubility due to prodrug approach.

Figure 1.3 Literature examples of permeability optimization.

BBB with reasonable accuracy. The BBB membrane is negatively charged and this favors permeability of basic amine-containing compounds that are positively charged at physiological pH. Implication of charge can be seen in comparing indomethacin and trifluoroperazine. Indomethacin, which has a pK_a of 4.18 is negatively charged, while trifluoroperazine, which has a pK_a of 7.8, is positively charged at physiological pH, which results in inability of indomethacin to cross the negatively charged BBB [22]. Strategies that improve intestinal permeability, such as increased lipophilicity, decreased H-bonding, decreased polarity, also improve BBB penetrability. Uptake of morphine across BBB was found to be 32-fold higher than its M6-glucuronide, which has ~150-fold lower lipophilicity [23]. In another example, the substitution of one $-OH$ group in morphine by a $-OCH_3$ in codeine reduced the intermolecular H-bonding and lipophilicity and increased BBB penetration increased by 10-fold. Replacement of

Figure 1.4 Introduction of intramolecular H-bonding to enhance BBB permeability.

both $-OH$ in morphine by acetates to form heroine resulted in a 100-fold increase in brain permeability [23]. Introduction of intramolecular H-bonding has been shown to be effective in making a compound more lipophilic, hence increasing CNS penetration (Fig. 1.4) [24].

In general, ways to improve solubility include (i) reduction of $\log P$ via introduction of ionizable groups, increase in H-bonding, increase in polarity, decrease in lipophilicity and (ii) decrease in crystal packing via introducing out-of-plane functional groups. However, some of these changes result in undesirable modulation of intestinal permeability which is favored by increased lipophilicity, reduced H-bonding (reduced PSA), and reduced polarity. It is often easier to fix solubility of compounds than permeability since solubility of a chemical series can be modulated over a million-fold range, while the difference between a poorly and highly permeable compound is only by ~ 50 -fold [5].

1.3.2 Metabolic Stability

The great majority ($>75\%$) of the marketed drugs are eliminated by metabolism. High metabolic liability usually leads to poor PK properties (high clearance, low exposure, short half-life, and low OBA), and therefore, it is desirable to have a metabolically stable compound, (except in cases of prodrugs) to ensure minimal variations in interindividual responses for its exposure and duration of action. Determination of metabolic stability, also commonly referred to as *in vitro* intrinsic clearance (Cl_{int}), is one of the key *in vitro* ADME parameters that is evaluated and optimized at a very early stage of discovery to transform a less desirable, metabolically unstable chemotype into one that has favorable Cl_{int} . Metabolic stability *in vitro* is also believed to predict hepatic clearance *in vivo*, which in turn is a major contributor to total body clearance of the majority of xenobiotics. High metabolic stability and hence low Cl_{int} are often desirable. In most cases, low Cl_{int} also leads to favorable PK properties such as good OBA and long half-life, which result in good exposure and desired duration of action, respectively. Compounds that possess high Cl_{int} are also more susceptible to drug–drug interactions (DDIs) and possess less-than-desirable exposure and duration of action required for therapeutic efficacy of a drug.

1.3.3 Plasma Protein Binding

PPB is believed to have a significant influence on the rate of drug diffusion between plasma and tissues (influx and efflux) [25] and therefore influence Cl and V_{dss} of

drugs. In general, it is desirable to avoid highly plasma protein bound drug since small changes in PPB of a highly bound drug can lead to significant fluctuation in its free fraction.

1.4 ISSUES IN DRUG DEVELOPMENT

1.4.1 Failure of *In Vitro*–*In Vivo* Correlation for Prediction of DDIs

In early stages of drug discovery, as actual human data are not available, results obtained from human subcellular fractions are extremely valuable in predicting the human PK parameters and assessing the potential of an NCE as a successful human drug candidate. But before a significant amount of effort is dedicated to optimize and modulate drug metabolism and pharmacokinetics (DMPK) properties of a new chemotype, it is very important to evaluate the ability of the *in vitro* ADME assays to predict the *in vivo* situation, that is, establish *in vitro*–*in vivo* correlations (IVIVCs) at very early stages of drug discovery. The following are some underlying reasons that are being made in predicting Cl_{hep} from Cl_{int} for the failure of IVIVCs [7]:

1. Assume that metabolism is the major route of Cl of the NCE.
2. Assume that liver is the primary organ responsible for the Cl (additional relevant *in vivo* clearance pathways, such as renal or biliary, that are not captured in *in vitro*).
3. Assume that cytochrome P450 (CYP)-mediated oxidative metabolism is the key metabolism pathway and contributions by other phase I and phase II enzymes, and hence DDI mediated by these, are nonexistent.
4. Failure to account for shift in major metabolic pathway *in vivo* as compared to *in vitro* (not predicted by *in vitro*).
5. Failure to account for formation of inhibitory (or inducing) metabolites *in vivo* (or vice versa).
6. Assume that Cl_{int} is similar in microsomes and hepatocytes *in vivo*.
7. Assume that enzyme expression and activities in isolated subcellular fractions is representative of those in the physiological milieu.
8. Assume that no uptake (not modeled by microsomes) or efflux transporters (not modeled by hepatocytes) are involved in drug uptake and Cl.
9. Failure to account for intestinal efflux.
10. Failure to account for effect of f_u in the intestine.
11. Uncertainty in quantitative effect of inhibitors toward intestinal clearance.
12. Failure to incorporate high PPB or concentration-dependent PPB of an NCE.
13. Failure to account for nonspecific binding of an NCE to microsomes, hepatocytes, or blood cells.
14. Failure to identify correct enzyme inhibition mechanism [reversible vs mechanism-based inactivation (MBI)] or inaccurate determination of k_{deg} in case of MBI.
15. Assume that the key kinetic parameters, such as K_i , k_{cat} , K_I , k_{inact} , k_{deg} , EC_{50} , and E_{max} , that are crucial in DDI assessment are similar *in vivo* to those determined *in vitro*.

16. Inaccurate determination of $f_m \times f_{m,CYP}$ (in the case of CYP-mediated DDI).
17. Effect of genetic polymorphism leading to interindividual variability in exposure, species, and gender difference in DME and transporter expression and activity.
18. Failure to quantitatively account for concurrent inhibition and induction by drugs (e.g., ritonavir and CYP3A4).
19. Lack of physiological scaling factors for transporters and DMEs other than CYPs [DMEs such as flavin monooxygenase (FMO), uridine glucuronosyl transferase (UGT), *N*-acetyl transferase (NAT), and sulfotransferase (SULT) and transporters such as Pgp, Breast cancer resistance protein (BCRP), Multidrug resistance-associated protein (MRP), Organic anion transporter (OAT), and Organic anion transporter polypeptide (OATP)].
20. Inability of *in vitro* systems to evaluate complex interplay of DMEs and transporters.
21. Assume that no atypical kinetics between the NCE and the enzyme responsible for its Cl.

It can be simply summarized that due to species differences in the expression levels, tissue localization, substrate specificity and gene regulation of transporters and DMEs, and extrapolation of data from *in vitro* studies and *in vivo* preclinical species to predict drug disposition *in vivo* in humans is very challenging.

1.4.2 Projection of Human PK

Accurate projection of human PK parameters (Cl, V_{dss} , and F) and efficacious dose is extremely valuable in drug discovery and ensures that the NCEs with poor PK properties or safety concerns (due to high dose requirement) are not selected as potential drug candidates for development. Over the past two decades, numerous methodologies using the drug metabolism and disposition data from *in vitro* human tissues such as microsomes or hepatocytes and *in vivo* preclinical studies have been developed, each with its own advantages and disadvantages [26,27]. Using these techniques, an overall success rate of 60–80% of compounds in prediction of human PK parameters within twofold of actual human PK parameters [26–28] has been achieved. Recently, Hosea *et al.* [29] have shown that the either single-species *in vivo* data or *in vitro* human liver microsomes can quantitatively predict human *in vivo* PK within twofold of actual values by conducting a retrospective analysis of 50 proprietary compounds for which *in vitro*, preclinical PK data and oral single-dose human PK data were available. The success rate of 60–80% is good to rank order the NCEs in drug discovery but is insufficient to discriminate closely related analogs within a series [28]. In drug discovery, the ability to predict the human PK of an NCE from *in vitro* and *in vivo* models with a reasonable degree of accuracy (<twofold variation) is one of the most challenging task.

Human PK projection can be performed via some common methods (Fig. 1.5) [7]: (i) allometric scaling of preclinical *in vivo* PK parameters; (ii) *in vivo* Cl projection from *in vitro* Cl_{int} ; (iii) species invariant time methods such as equivalent time, kallynochrons (elementary Dedrick plot), apolysichrons, dienetichrons, or syndesichrons, each of which are some modifications of the elementary Dedrick plot method; and (iv) C_{ss} -mean residence time method. For human OBA estimation, the fraction of dose appeared into the portal vein ($F_g \times F_a$) of each preclinical animal species can be calculated, the average of which can be used to estimate human $F_g \times F_a$. This estimate

Simple allometry:	BW = body weight
	MLP = maximum life span
$Cl = a BW^b$	a = coefficient (log a is the y -intercept) of Cl
$V_{dss} = c BW^d$	b = exponent (b is slope of log-log plot of Cl and BW) of Cl
	c = coefficient (log a is the y -intercept) of V_{dss}
	d = exponent (b is slope of log-log plot of V_{dss} and BW) of V_{dss}

ROE used for Cl prediction:

if $0.55 < b < 0.7$ then simple allometry best (above equation)

if $0.71 < b < 0.99$ then $Cl \times MLP = a BW^b$

if $b \geq 1$ then $Cl \times \text{brain weight} = a BW^b$

Elementary Dedrick plot	Complex Dedrick plot	Dienetichrons
$Y = \frac{\text{Concentration}}{(\text{Dose}/BW)}$	$Y = \frac{\text{Concentration}}{(\text{Dose}/BW^d)}$	$Y = \frac{\text{Concentration}}{(\text{Dose}/BW^d)}$
$X = \frac{\text{Time}}{BW^{1-b}}$	$X = \frac{\text{Time}}{BW^{d-b}}$	$X = \frac{\text{Time}}{MLP \times BW^{1-b}}$

Calculation of OBA in human

$$f_a \times f_g = \frac{F_{PO, \text{animal}}}{\left(1 - \frac{Cl_{\text{hep, animal}}}{Q_{h, \text{animal}}}\right)}$$

$$F_{PO, \text{human}} = f_a \times f_g \times \left(1 - \frac{Cl_{\text{hep, human}}}{Q_{h, \text{human}}}\right)$$

Cl_{hep} = hepatic clearance
 Q_h = hepatic blood flow
 f_a = fraction absorbed
 f_g = fraction escaping gut first pass
 F_{po} = bioavailability

Figure 1.5 Various methods used to predict human pharmacokinetics.

can be combined with the predicted human Cl , obtained by methods outlined above, to yield the predicted human OBA. Human OBA values can further be used to estimate the predicted human exposure at a desired dose. It is highly advisable to use multiple scaling methods to obtain a range of values for each of the predicted PK parameters.

1.4.3 Prediction of Human Metabolites

Metabolism facilitates the removal of chemicals from the body. In general, metabolites are pharmacologically less active and less toxic than their corresponding parent compound. However, the biotransformation reactions can sometimes lead to undesirable consequences, such as too rapid drug clearance, formation of pharmacologically active metabolites, DDIs via inhibition or induction of DMEs, and/or formation of toxic metabolites. In addition, drug-metabolizing ability is age dependent, influenced by the genetics of the individual (polymorphisms), reduced by certain disease states and can be altered when coadministered with other drugs.

Knowledge of the metabolic site(s) of an NCE in early drug discovery is essential for selecting compounds with favorable PK credentials and aiding medicinal chemists in modifying metabolic “soft spots” and to design better, lower metabolic-clearance analogs. In development, elucidation of biotransformation pathways of a drug candidate by identifying its circulatory and excretory metabolites is vitally important to understand its physiological effects. In discovery, metabolite characterization is performed *in vitro* using hepatic subcellular fractions from human and multiple animals to guide species selection for safety assessment studies in preclinical development. The species that most closely resembles human with respect to metabolite profile are selected as the preferred species for toxicity evaluations. Metabolite identification is, therefore, very important in drug discovery for the NCE progression and should be incorporated at very early stages to eliminate structural liabilities in the later stages of drug development. Efforts directed to improve metabolic stability are represented by some selected examples from literature, as shown in Fig. 1.6 [7].

Structure elucidation of metabolites may also indicate the formation of reactive intermediates, which have the potential to bind to biomolecules and cause immune-mediated toxicity. Knowledge of formation of reactive metabolites in the early drug discovery stages is very helpful in minimizing the risk associated with reactive intermediates/metabolites. It is postulated that reactive metabolites bind to crucial proteins and result in either direct organ damage or the modified protein elicits a hapten-mediated immune response. A complex cascade of signaling results in unpredictable toxic responses, also called *idiosyncratic toxicity* or *idiosyncratic drug*

Figure 1.6 Examples to highlight structure optimization to improve metabolic stability: compounds shown on right side of the arrows are the metabolically stable version of the compounds on the left of the arrows. *Represents sites of metabolism that were blocked.

reaction (IDR). It is called idiosyncratic because the toxicity is not only unpredicted but also occurs in 1 of 1000 patients receiving the drug/NCE, thus making it virtually impossible to detect earlier at the preregistration phase. IDR risk is a significant liability and increases cost and risk of development of an NCE. It is therefore crucial to detect reactive metabolites very early on during the drug discovery phase and strategically remove the toxicophore moiety to avoid costly drug failures in development or worse, postmarketing. Structural characteristics of compounds forming reactive intermediates/metabolites have been extensively reviewed [7,30]. Compounds containing functional groups such as anilines, nitrobenzenes, benzyl/cyclopropyl amines, thiophenes, furans, thiazoles, sulfonylureas, hydrazines, carboxylic acids (those with α -protons), methylenedioxy, alkynes, terminal alkenes, halogenated hydrocarbons, and Michael acceptors [7,30] are all recognized to produce reactive metabolites.

In some cases, metabolites, due to structural similarity with their parent, could also be pharmacologically active, which results in disconnect between pharmacokinetics/pharmacodynamics (PK/PD) data. Several active metabolites have been developed and marketed as drugs. The examples of active metabolites of marketed drugs that have been developed as drugs include acetaminophen, fexofenadine, desloratadine, cetirizine, oxazepam, oxyphenbutazone, morphine-6-*O*-glucuronide, and minoxidil sulfate. Each of these drugs provides a specific benefit and has a better PK and/or safety profiles over the parent molecule.

1.4.4 Drug–Drug Interactions

Another major challenge in drug discovery is DDI. In recent years, several drugs have been withdrawn from the market in the United States and Europe due to serious adverse reactions as a result of significant DDIs [31]. DDIs are caused when the PK of one drug is influenced by a coadministered drug. The consequences of these DDIs can range from loss of therapeutic efficacy to the introduction of toxic effects. Most marketed drugs are eliminated from the body at least in part by metabolism, and many of the DMEs are inducible and can be inhibited; therefore, inhibition and/or induction of DMEs by one drug could have a significant effect on the disposition of another drug. The NCEs can either be perpetrators or victims of such interactions, and early evaluation of NCEs for their potential to function in either capacity is critical to the development of new drug candidates. The DDI risk is more profound if the victim drug has high intrinsic clearance or is selectively cleared via one major pathway. So, development of an NCE that is either itself a modulator of DME or affected by modulation of the DMEs, especially if the NCE also possesses high Cl_{int} , is not favorable. Therefore, inhibition and induction of DMEs by an NCE and the DME responsible for its metabolism are routinely assessed at very early stages of the drug discovery.

DDIs should not be viewed as solely undesirable as there have been several cases where PK of one drug has been modulated by another via a well-planned design to improve the exposure (and hence the efficacy) of the affected drug [7]. Kaletra is a coformulation of lopinavir and ritonavir, whereby ritonavir-mediated CYP3A4 inhibition results in higher plasma levels of lopinavir and boosts its anti-HIV protease activity. Ketoconazole (KTZ), a potent CYP3A4 inhibitor, is commonly used in combination with cyclosporine A (CsA) to enhance the immunosuppressive properties of

the latter as a result of increase in CsA exposure to due KTZ-mediated inhibition of CsA metabolism.

1.4.4.1 Drug-Metabolizing Enzyme Inhibition. Inhibition of enzymes can be reversible or irreversible and always results in reduction of intrinsic clearance of the pathway that is inhibited [32]. Reversible inhibition, also known as *direct inhibition*, can be typically classified as competitive, uncompetitive, noncompetitive, or mixed, with competitive inhibition being the most commonly observed pathway of inhibition. *In vitro* inhibition studies are valuable in assessing potency of an NCE as an inhibitor as given by $[I]/K_i$ ratio (details in Section 1.5.2). In addition to the $[I]/K_i$ ratio of the inhibitor, contribution of the inhibited pathway to the overall metabolism of an NCE, $f_m \times f_{m,CYP}$ (f_m = fraction of the NCE cleared via metabolism, $f_{m,CYP}$ = fraction of metabolism via CYP), enzyme interaction at the intestinal site and parallel routes of metabolism, all play a vital role in risk assessment due to potential DDI. In situations where an NCE can inhibit multiple CYPs with $[I]/K_i$ ratio >0.1 for each of the CYP-mediated pathways, a rank order approach is recommended for conduct of clinical DDI [7,33].

For MBI, *catalytic bioactivation of an NCE by an enzyme* is a *prerequisite*. This results in irreversible inhibition of the enzyme, and therefore, potency of both these types of inhibition increase over time (with preincubation). MBI of CYPs have been extensively investigated and the presence of functional groups [7,30] such as aniline, nitrobenzene, hydrazine, benzyl/propargyl/cyclopropyl amine, hydantoin, thioureas, thiazole, furan, thiophene, epoxides, methylene dioxy, methyl indoles, alkyne, isothiocyanate, and terminal alkenes, on an NCE warrants immediate and early assessment of inactivation potential of the NCE to avoid severe DDI liability in late stage development. It must be borne in mind that if an NCE does possess a structural alert, it does not automatically imply that it will be a potent inhibitor. Distinguishing MBI from simple reversible inhibitor is critical in predicting a clinical DDI, since applying a reversible inhibition model to an MBI may result in significant underprediction of a DDI risk.

The magnitude of a DDI is dependent on the degree of contribution of the clearance pathway that is modulated (inhibited or induced); higher the fraction of the dose metabolized by the enzyme that is modulated, greater is the magnitude of DDI. It is very favorable for an NCE to have multiple pathways of clearance, so that when one of these is affected, it is compensated for by the other pathways. Drugs that are metabolized by polymorphic enzymes (e.g., 2D6, 2C9, and 2C19) are prone to risk of either lack of drug efficacy (due to increased clearance of the drug in the rapid metabolizers) or increased toxicity (due to accumulation of drug in the poor metabolizers) and may warrant a dose adjustment based on the population genotype. Hence, identifying major pathways that are responsible for the clearance of an NCE is crucial in eliminating DDI risk later on in drug development [7]. A significant amount of work has been done in the area of the CYP enzyme phenotyping due to the availability of cDNA-expressed enzymes, normalization methods, and isoform-specific substrates and inhibitors (chemical and antibody) [34]. CYP phenotyping involves rigorous kinetic analysis of metabolite formation, to give an estimate of $f_{m,CYP}$, which represents *in vivo* contribution of a particular isoform(s) toward a biotransformation pathway of an NCE. The magnitude of the product of $f_{m,CYP}$ and f_m reflects the propensity of an NCE to be subjected to DDI. Higher the value of $f_{m,CYP} \times f_m$, higher will be the risk

Exposure change due to inhibition or induction of CYP-metabolism

$$\frac{AUC_{PO, \text{inhibitor}}}{AUC_{PO, \text{control}}} = \frac{f_{g, \text{inhibitor}}}{f_{g, \text{control}}} \times \frac{1}{\left(\frac{f_m f_{m, \text{CYP}}}{Cl_{\text{int, control}} / Cl_{\text{int, inhibitor}}} \right) + [1 - (f_m f_{m, \text{CYP}})]}$$

$$Cl_{\text{int, control}} / Cl_{\text{int, inhibitor}} = 1 + [I] / K_i \text{ for reversible competitive or noncompetitive inhibition}$$

$$= 1 + \frac{k_{\text{inact}}}{K_i} \cdot \frac{[I]}{k_{\text{deg}} \text{ for mechanism-based inhibition}}$$

AUC = exposure

f_g = fraction surviving gut first pass

f_m = fraction of total clearance due to all CYP-metabolism

$f_{m, \text{CYP}}$ = fraction of total CYP-metabolism catalyzed by the inhibited CYP isoform

$[I]$ = inhibitor concentration

k_{inact} = rate constant of CYP inactivation

K_i = half maximal inactivation rate

K_i = dissociation constant of enzyme-inhibitor complex

Exposure change due to inhibition of intestinal metabolism (for drugs that this pathway is significant)

$$\frac{AUC_{PO, \text{inhibitor}}}{AUC_{PO, \text{control}}} = \frac{Q_{gm} + f_u Cl_{\text{int, gm}}}{\left(Q_{gm} + \frac{f_u \cdot Cl_{\text{int, gm}}}{[1 + (I_{gm} / K_i)]} \right)} \cdot \left(\frac{1 + I_u}{K_i} \right)$$

I_{gm} = unbound inhibitor concentration in intestine
 I_u = unbound inhibitor concentration in liver
 Q_{gm} = blood flow to GI mucosa
 f_u = fraction unbound of inhibitor in plasma
 K_i = inhibition constant

Figure 1.7 Exposure change in the presence of inhibitor.

of DDI. Changes in exposure of an NCE in the presence and absence of a modulator (inhibitor or inducer) can be simulated by the equation shown in Fig. 1.7 [7].

Estimation of f_m can be most accurately made from a human radiolabel study. A good estimate can also be obtained from a single-dose phase I human study. In many projects, due to the absence of human data in early stages of development, estimates of f_m are not available and $f_{m, \text{CYP}}$ data are used to guide clinical DDI studies via a “rank order” approach [33].

Unfortunately, the assessment of the contribution by other enzymes such as FMO, SULT, and UGT are limited to qualitative evaluation only due to limitation of availability of cDNA-expressed enzymes, normalization methods, and isoform-specific substrates and inhibitors.

1.4.4.2 Drug-Metabolizing Enzyme Induction. DDI can also occur through induction of nuclear receptors and modulation of the transcription and the expression of DMEs and transporters. This results in elevation of enzyme levels or increase in activity, which leads to faster clearance of the NCEs. Faster clearance of an NCE leads to lower than expected exposure, as demonstrated by significant decrease in exposures of several drugs such as midazolam, amitriptyline, cyclosporine, digoxin, indinavir, irinotecan, warfarin, phenprocoumon, alprazolam, dextrometorphane, simvastatin, and ethinylestradiol in the presence of St. John’s wort, which has been shown to be a potent inducer of both CYP3A4 and Pgp [7]. Reduced exposure sometimes severely compromises therapeutic efficacy as seen with coadministration of cyclosporine (CYP3A4 substrate) and rifampin (potent CYP3A4 inducer) to organ transplant patients. Induction

of DMEs and transporters is regulated by a large family of nuclear receptors, such as aryl hydrocarbon receptor (AhR), pregnane X receptor (PXR), constitutive androstane receptor (CAR), glucocorticoid receptor (GR), and peroxisome proliferator-activated receptor- $\alpha/\beta/\gamma$ (PPAR- $\alpha/\beta/\gamma$) [35]. Owing to regulation of several DMEs and transporters via common receptors, it is advised to monitor a few sentinel CYP isoforms that are indicative of activation of the principle nuclear receptors. CYP1A2, 2B6, and 3A4 induction are suggested to be indicative of activation of AhR, CAR, and PXR, respectively [36].

1.4.4.3 Interplay between Drug-Metabolizing Enzymes and Transporters. There are numerous examples in the literature where a DDI may be the result of modulation of a DME, as exemplified by the DDI between terfenadine-KTZ, fluvoxamine-astemizole, cisapride-erythromycin, statins-protease inhibitors, felodipine-nifedipine, codein-quinidine, β -blockers-ritonavir, and rifampin-cyclosporine/simvastatin/verapamil/midazolam. Sometimes it may be due to modulation of transporters such as those exemplified by digoxin-quinidine, probenecid-acyclovir/allopurinol/cephalosporins/ciprofloxacin, and talinolol/verapamil. More often the DDIs result from an intricate interplay of modulation of both DMEs and transporters. Gemfibrozil causes six- to eight fold increase in exposures of coadministered drugs such as cerivastatin and repaglinide (antidiabetic) not only due to inhibition of uptake inhibitor OATP1B1 but also due to inhibition of CYP2C8, CYP3A4, and Pgp. Increase in plasma and Cerebrospinal fluid (CSF) concentration of the HIV protease inhibitors ritonavir and saquinavir, due to coadministration with KTZ, has been attributed to potent inhibition of both CYP3A4 and Pgp by KTZ.

Transporters can also modulate the extent of metabolism of an NCE by affecting its exposure of an NCE to the DMEs [37,38]. Ability of transporters to modulate metabolism is also dependent on the Biopharmaceutics Classification System (BCS) class of the NCE under investigation [37,39]. Uptake or efflux transporters are unlikely to affect metabolism/exposure of class 1 (high solubility and high permeability) compounds, while uptake and efflux transporters are expected to modulate metabolism/exposure of NCEs, belonging to class 2 (low solubility and high permeability), class 3 (high solubility and low permeability), and class 4 (low solubility and low permeability).

1.4.4.4 Plasma Protein Binding. It is a common concern when the free drug concentration of a highly bound drug A increases due to PPB displacement by a strong binding drug B. The increased free drug A's concentration could potentially cause toxicity (due to more free fraction available to interact with target receptors) and may need dose adjustment. In addition to target-mediated efficacy/toxicity, PPB information is also helpful to estimate unbound/effective concentration of drugs that mediate inhibition of DMEs and transporters. Disease models are extensively validated in animals to progress a compound into development. *Unbound drug concentration* and therefore PPB across species is very informative in establishing safety margins and guiding selection of First in human (FIH) dose and human efficacious dose.

CNS drugs have been highlighted to be extremely sensitive to PPB and PPB-displacement situation. It must be recognized that BBB transporters, permeability, and protein binding to blood versus brain *all* play an equally important role in the rate and extent of drug uptake into CNS [40]. Increase in nonspecific binding in brain

tissue is considered to be a driving force to overcome effect of efflux transporters and therefore, Pgp substrates can still penetrate the brain because partition into brain tissue can provide a significant drug concentration gradient at the BBB to overcome effects of efflux transporters. Usually, increase in lipophilicity of a drug, not only increases its CNS penetration/permeability, but it also increases its nonspecific binding to brain tissue, resulting in lesser unbound/pharmacologically active drug available in brain for efficacy. Several examples of compounds that demonstrate high target affinity, high plasma concentration, and high brain/plasma (B/P) ratio, and yet fail to show efficacy, warrant extreme caution in optimization of the total B/P ratio only, for CNS drugs. CSF has been widely believed to be a surrogate for estimation of the unbound, pharmacologically active drug concentration in CNS [41]. Owing to a very low protein content of CSF, drug–protein binding in CSF is assumed to be negligible and CSF concentration is considered to represent the unbound drug in CNS, which is equal to the unbound drug concentration in plasma at steady-state equilibrium.

1.4.5 Polymorphism of Drug-Metabolizing enzymes

Many of the DMEs show genetic polymorphism, which can influence the levels of expression, enzyme stability, and catalytic properties [42–45]. Polymorphisms that have been discovered in the genes of CYP2C19, CYP2D6, UGT1A1, NAT, and thiopurine methyl transferase (TMT) are particularly good examples of the importance of knowing polymorphisms in DMEs and the challenges in the development of NCEs as new drugs. Genetic variability in DMEs is a significant contributor to the variability in human drug PK. Hence, knowledge of the enzymes involved in clearance of NCEs along with knowledge of polymorphisms that exist for these enzymes is critical to the development of safer drug.

1.4.6 Drug-Induced Toxicity

Drug-induced toxicity remains one of the major reasons for failures of new pharmaceuticals and for the withdrawal of approved drugs from the market. The combined *in vitro*, *in vivo*, and *in silico* computational models have been used to assess the toxicity of the NCEs. While using these approaches, many compounds that might have serious adverse reactions associated with them are effectively eliminated before reaching the clinical trials; some toxicities such as those caused by idiosyncratic responses, however, are not detected until the drug is in late stages of clinical trials or have become available to the market. One of the proposed mechanisms for the development of idiosyncratic drug toxicity is the bioactivation of drugs to form the reactive metabolites by DMEs (Section 1.4.3). Efforts are being made to detect these reactive metabolites in the early stages of drug development [46].

1.4.7 Metabolites in Safety Testing

In February 2008, Food and Drug Administration (FDA) issued the final Guidance for Industry: Safety Testing of Drug Metabolites. The guidance recommends that the exposure of human metabolites that exceed 10% of the parent drug exposure [ICH (International Conference on Harmonisation) revised to total drug-related material] at steady state should be equal or higher in at least one of the preclinical animal species be used for long-term safety assessment [47,48]. Additional toxicological testing on

metabolites that display higher exposure in humans than preclinical animal species may be required by direct administration of metabolites to the test animals. Therefore, metabolite safety qualification strategy needs to be established as soon as practical in drug development. There are a number of examples when human metabolism was quantitatively different from preclinical species.

1.5 ADME ASSAYS IN DRUG DISCOVERY

Multiple *in silico*, *in vitro*, and *in vivo* ADME studies have been developed and implemented in various stages of the drug discovery to weed out weak candidates and to select a compound with favorable PK properties for further development. Table 1.1 summarizes some of the commonly used ADME assays that DMPK scientists rely on to not only help in the iterative screening of compounds in discovery but also for risk mitigation as well as to gain insight into mechanism of certain ADME pathway or process. A list of useful guidances and white papers for the design and conduct of metabolism and DDI studies are described in Table 1.2 [47–55].

1.5.1 *In Silico*

Availability of experimental data, molecular descriptors (molecular size and shape, hydrophilic and hydrophobic regions, hydrophilic and lipophilic balance, and H-bond donors and acceptors), and statistical analysis methods (multiple linear, partial least squares, artificial neural nets, Bayesian neural networks, and clustered regression) are the three essential prerequisites for *in silico* modeling. *In silico* models for solubility take into account log *P*, melting point, crystal packing, intrinsic solubility, and ionization effects [56–60]. From the simple general solubility equation, to more complex models based on Monte Carlo simulations using 2D or 3D properties, and fragmental or atom-based or quantum-chemical methods have all been used to predict aqueous as well as Dimethyl sulfoxide (DMSO) solubility of compounds with fair accuracy. There are several programs (ACD/logs, SLIPPER, CSlogWS, KLOGS, CERIUS, and WSKOWWIN) available for these predictions and are highly recommended for solubility prediction in early discovery [61].

Molecular descriptors such as H-bond donors and acceptors, hydrophobic groups, aromatic rings, and basic nitrogen atoms are all important for the development of permeability and Pgp substrate models [61]. Computational Volsurf-based model [62], conformation-dependent, GRid-Independent descriptors (GRIND) descriptor method, and recent QSAR models [63] have all been valuable in aiding medicinal chemists to optimize permeability in drug discovery stages. Recent development in predictive models for BBB penetration has also gained significant popularity, which is also directed to gain better insight into transporters at the BBB junction [64,65]. Methods include 2D-QSAR techniques, built on pharmacophore modeling using Catalyst, DISCOtech, and 3D-QSAR techniques, using SYBYL, comparative molecular field analysis (CoMFA), and comparative molecular similarity index analysis (CoMSIA).

Composite QSAR models that incorporate solubility and permeability and programs (iDEA and GastroPlus) have been very useful to predict fraction of dose absorbed and bioavailability [66]. Bioavailability predictions are not very simple since it necessitates integration of absorption prediction (combination of solubility and permeability) and first-pass metabolism (gut and liver). QSAR models and adaptive fuzzy portioning

TABLE 1.1 List of Commonly Used ADME Assays Used in Various Stages of Drug Discovery and Development

Parameter	Type	Method	Throughput
Solubility	Kinetic	Nephelometry	High
		Direct UV	High
		Turbidimetry	High
	Thermodynamic	Equilibrium shake flask	Low
		Potentiometric	Low
Permeability	Passive diffusion	Artificial membrane-based (IAM and PAMPA)	High
		Cell-based (Caco-2, MDCK, LLC-PK1, and CHO)	Moderate
		Cell-based Calcein-AM	High
	Transporter assisted	Inverted membrane vesicle-based ATPase	High
		Cell-based (Caco-2, MDCK, LLC-PK1, CHO, HEK293, KB-V-1, and MCF-7)	Moderate
		Transient transfection (oocytes, CHO, and COS)	Moderate
		BMECs for BBB	Moderate
	Rate of absorption	Gene KO animal studies (<i>in vivo</i>)	Low
		<i>In situ</i> tissue (liver, intestine, and brain) perfusion	Low
		Intraduodenal and portal vein cannulated rats (<i>in vivo</i>)	Low
Metabolism	Clearance	cDNA-expressed enzymes	High
		Subcellular fractions (microsomes and S9)	High
		Cell-based (fresh or cryopreserved hepatocytes)	Moderate/high
	Enzyme Inhibition	cDNA-expressed enzymes	High
		Subcellular fractions (microsomes and S9)	High
		Cell-based (cryopreserved hepatocytes)	Moderate/high
	Enzyme induction	Liver slices	Low
		Reporter gene assay (PXR binding and transactivation)	High
		Cell-based (sandwich-cultured) hepatocytes	Low
	Reaction phenotyping	cDNA-expressed enzymes	High
		Subcellular fractions (microsomes and S9)	High
		Cell-based (cryopreserved hepatocytes)	High
	Metabolite ID	Subcellular fractions (microsomes and S9)	High
		Cell-based (cryopreserved hepatocytes)	High

(continued overleaf)

TABLE 1.1 (Continued)

Parameter	Type	Method	Throughput
PPB	N/A	Biological matrices (plasma, bile, and urine)	Moderate
		Biacore technology (fluorescence spectroscopy)	High
		Chromatography and capillary electrophoresis	Moderate
		Ultrafiltration	High
		Ultracentrifugation	High
		Equilibrium dialysis (traditional/rapid-RED)	Low/high
		Microdialysis (<i>in vivo/in situ</i>)	Low

(AFP) models have been observed to yield a 60–65% prediction at best [67,68]. *In silico* intestinal device (ISID) model has also been developed to model absorption for compounds that are dual substrates of CYP and Pgp [69].

QSAR models to predict drug metabolism have been extensively developed using various statistical techniques [MLR (Multiple Linear Regression), PLS (Partial Least Square), NBC (Naïve Bayes Classifier), k-NN, SOM (Self Organizing Map), RP (Recursive Partitioning), ANN (Artificial Neural Networks), and SVM (Support Vector Machines)] [70–72]. A recent MLR approach for human hepatic clearance prediction using *in vitro* experimental data and six molecular descriptors (MW, number of total atoms, number of aromatic rings, number of single bonds, TPSA, and SKlogP) yielded ~85% success [70]. Random Forest and Bayesian methods [based on MOE (Mixture of Experts) and E-state descriptors] to predict human microsomal stability have also yielded about 75–80% prediction success. Availability of X-ray crystallographic structures of mammalian CYP enzymes has prompted development of ligand- or CYP enzyme-based 3D-QSAR, quantum mechanics (QM), and pharmacophore models [73], which have predicted compounds' ability to be CYP substrates with reasonable accuracy. Softwares such as MetabolExpert, META, METEOR, and MetaSite are readily available to discovery teams for prediction of metabolic sites. Significant effort has been directed toward developing *in silico* models for CYP inhibition especially for CYP3A4 and 2D6, since these are the two isoforms that metabolize a vast majority of the marketed drugs. Several approaches such as RP ensemble method, PLS and ANN models, MLR analysis, NN, and Bayesian methods have been developed, some with as high as 99% prediction accuracy of CYP inhibitors. Pharmacophoric models and 3D-QSAR models (CoMFA and GOLPE/GRID) have also been used to predict CYP inhibitors with ~70% accuracy. It is interesting to note that for different CYP isoforms, different molecular descriptors are important, based on physicochemical nature of substrate binding at the CYP-active site. For example, molecular volume is important for CYP1A2 inhibition, while H-bond acceptor and hydrophobicity are more important for CYP2C9 models and MW, H-bonding capacity and number of aromatic atoms are more important for CYP3A4 models [74].

In silico modeling of CYP induction is very challenging due to the requirement of availability of crystal structure of nuclear receptors along with well-understood structural biology [75]. In addition, due to large binding pocket of some of the receptors, especially PXR, combined with the ability of the ligands to bind to several regions of the nuclear receptors further complicates modeling. Crystal structure of PXR, along with experimental data, has been used to build *in silico* PXR-binding model. Introduction of polar groups in the regions that show high affinity to the hydrophobic binding pocket of PXR, as well as making compounds more rigid to prevent binding, have been successful strategies, to synthesize compounds that do not bind to PXR. Pharmacophore modeling of hCAR also was able to model hCAR ligands with reasonable success.

In general, for CYPs and nuclear receptors, flexibility of their active sites, promiscuous nature due to which they accommodate very diverse ligands, the presence of multiple binding sites, binding modes, binding orientation, ability of ligands to alter protein structure, unavailability of unambiguous structural biology mechanism for some pathways, and the presence of multiple metabolic pathways have all contributed to make *in silico* modeling of CYP inhibition and CYP induction very challenging.

In silico metabolism prediction softwares such as Meteor and Metasite, coupled with several metabolite identification data processing softwares (offered by Agilent,

Applied Biosystems, and Thermo Scientific), have made biotransformation prediction for an NCE much easier. However, a strong organic chemistry background coupled with good expertise in liquid chromatography (LC)/tandem mass spectrometry (MS/MS) methodologies and data interpretation are the key prerequisites for successful metabolite identification.

1.5.2 *In Vitro* Methodology

1.5.2.1 Solubility. Solubility measurements can be of two different types—kinetic and thermodynamic [67]. For kinetic solubility, it is common to start with a stock solution of the compounds of interest in organic solvent, mostly DMSO, which is then diluted in buffer over a wide concentration range and solubility of compounds assessed via UV or optical light scattering methods. Kinetic solubility measurements are quite common in early discovery for rank ordering compounds and are most valuable for assessing solubility of compounds in a certain *in vitro* assay (biochemical or cellular) medium. Thermodynamic solubility measurements of NCEs are usually performed, in their solid state and hence this type of solubility measurements takes into account disruption of crystal lattices and dissolution process of the compounds. Although the gold standard for solubility measurements, thermodynamic solubility measurements are quite labor intensive and variations of a classical thermodynamic solubility assay are gaining popularity, one of these involves starting with DMSO stocks as in kinetic solubility measurements, but the DMSO is completely removed to dry the compound down to a powder form before adding the buffer [76].

1.5.2.2 *Permeability/Transporters.*

1.5.2.2.1 Cell-Based. Several cell-free and cell-based systems have been employed to investigate permeability and role of transporters in permeability of an NCE [61]. The cell-free parallel artificial membrane permeability assay (PAMPA) has been widely used as a high throughput, inexpensive, and simple tool to screen discovery compounds for their potential for passive permeability [77]. Caco-2 cell permeability is a widely used, “gold standard,” *in vitro* screening and investigative assay to rank order compounds in the discovery stages, for their intrinsic permeability across intestinal epithelium and to investigate basic mechanistic studies involving absorptive transport (paracellular vs transcellular transport and the presence of saturable active transporter) [78]. Madine–Darby canine kidney (MDCK) cells, Chinese hamster ovary (CHO) cells, human embryonic kidney (HEK) 293 cells, porcine proximal tubular epithelial (LLC-PK1) cells, human metastatic breast cancer cells (MCF-7), and Multidrug resistance protein (MDR) human KB carcinoma (KB-V-1, human cervical carcinoma/epidermoid cell line) cells are some of the other commonly used cell lines, transfected with transporter(s) of interest, to perform diagnostic/mechanistic transporter studies [79]. Cultured brain microvessel endothelial cells (BMECs), which form a confluent monolayer and retain morphology and functional capacity of BBB, are very valuable in investigating transport mechanisms involving passive diffusion and polarized uptake/efflux across the BBB [80]. Double/triple transfected cell lines (most of the time with one uptake and another efflux transporter) such as MDCKII-BCRP/OATP-B, MDCKII-NTCP/BSEP, and MDCK II-BCRP/OATP2 are very useful in investigating synergistic effect of uptake and efflux transporters across intestinal epithelium and hepatobiliary membrane [79].

1.5.2.2.2 Membrane-Based. Membrane-based transporter assays are important tools to study transporter-mediated interaction/disposition of drugs [61]. ATPase assay is a plasma membrane-based simple, rapid, and high throughput assay that can assess whether a compound is a substrate or inhibitor of ATP-binding cassette ABC transporters [81,82]. The ATPase assay endpoint is release of inorganic phosphate due to adenosine triphosphate (ATP) hydrolysis. The release of inorganic phosphate is monitored via a simple colorimetric assay. However, this assay cannot be used for Solute carrier transporters (SLC) transporters since SLC transporters lack ATPase activity. Isolated membrane vesicles, such as the rat liver canalicular membrane vesicle (CMV) [83] and rat intestinal and renal brush-border membrane vesicles (BBMV) [84], are very useful for studying ABC transport. Inside-out vesicles present ATP-binding site to the NCEs being tested and substrates of ABC transporters are taken up in an ATP-dependent process across the vesicles.

1.5.2.2.3 Oocytes. *Xenopus laevis* oocytes, transfected with SLC transporters, have also been useful for studying SLC-transporter-mediated uptake studies. Recently, MDR1-mediated drug transport has also been investigated in this model [85]. Hepatic disposition of irinotecan and its glucuronide metabolite and the effect of OATP1B1 polymorphism on its uptake were investigated using this model [86].

1.5.2.2.4 B-CLEAR. B-CLEAR hepatocytes model has been very useful in investigating biliary excretion of compounds—primary sandwich-cultured human hepatocytes (SCHHs), used in this model, permit the canalicular network to be formed and maintained [87]. Since the uptake and efflux transporters are present in the SCHHs, this model is very valuable not only for biliary excretion prediction of compounds but also for interspecies differences in hepatobiliary disposition (rat vs human), hepatobiliary—transporter-mediated DDI prediction and hepatobiliary toxicity.

1.5.2.3 Metabolism. Since liver is considered to be the primary site of metabolism for the majority of the xenobiotics and endogenous compounds, subcellular fractions, intact cells, and tissue slices, derived from liver, are powerful *in vitro* tools and are routinely used in the pharmaceutical industry to assess the metabolism of NCEs [7]. Subcellular fractions (liver microsomes, microsomes with cDNA-expressed metabolic enzymes, and S9-homogenates) from a variety of rodent and nonrodent animal species, along with human, are commercially available, easy to handle, and amenable to long-term storage. Liver microsomes are the most commonly used *in vitro* system and although they contain enzymes located only in the endoplasmic reticulum, such as CYP, FMO, UGT, and esterases, microsomes are viewed as a very good system for assessing oxidative potential of NCEs. cDNA-expressing microsomes have the advantage of expressing high concentration of one particular enzyme/isoform and are often used when assessing the DDI potential of NCEs. S9 homogenates, although have the advantage over microsomes of containing both oxidative and conjugative enzymes, have not attained as much popularity as the microsomes due to relatively lower enzyme activity levels. Predictability of *in vivo* clearance from the subcellular-fraction-derived *in vitro* Cl_{int} is often questionable because of the need to fortify the subcellular fraction with supraphysiological proportions of cofactors [e.g., NADPH (Nicotinamide adenine dinucleotide phosphate), NADPH reductase, $MgCl_2$, and cytochrome b5]. In spite of the mixed success of *in vivo* Cl_{int} predictions from subcellular-metabolism-derived data (more discussed in the IVIVC section later), it is well accepted that in the early

stages of drug discovery, the subcellular fractions play an extremely important role in rank ordering compounds. Intact cells (cryopreserved and fresh hepatocytes) and tissue slices have certain distinct advantages over subcellular fractions in that they possess intact cellular morphology and are therefore believed to mimic the *in vivo* situation more closely than subcellular fractions. It must be remembered that cryopreserved hepatocytes, although mimics compound uptake through the cell membrane as in an *in vivo* situation, however, due to internalization of efflux transporters, compound efflux is not captured. They also do not need any added cofactors to facilitate metabolism, and metabolism studies can be carried out over much more extended time periods than with the subcellular fractions. However, handling and storage of intact cells and especially tissue slices are also lot more complicated than subcellular fractions, which are by far the most commonly used *in vitro* tools to evaluate metabolism of NCEs in drug discovery stages. Several excellent reviews have been published recently to compare the advantages and disadvantages of these various *in vitro* models and overview of experimental conditions required.

1.5.2.3.1 Prediction of Human PK. Metabolic stability at the early discovery stages is commonly expressed as either percent parent compound remaining after incubation for a certain period of time (up to 30 min for microsomes and up to 2/4 h for hepatocytes), but it is highly advisable to translate the percent parent remaining to Cl_{int} (Eq. 1.1, Fig. 1.8). Commonly used methods to calculate Cl_{int} involves determination of either the *in vitro* half-life ($t_{1/2}$) or by calculating the enzyme kinetic parameters; maximum velocity of the enzymatic reaction (V_{max}), and substrate concentration yielding the half of V_{max} (K_m), as shown in Equation (2) in Fig. 1.8 [7].

To gain a better physiological perspective of Cl_{int} , it is further converted to Cl_{hep} via several different methods, such as the well-stirred (Eq. 3, Fig. 1.8) or venous equilibrium model, sinusoidal perfusion or parallel tube model, and physiological-based dispersion mode. In most cases, when the NCE in question is a low clearance compound ($E < 0.25$), Cl_{hep} predicted from either well-stirred or parallel tube models will not be much different. However, for a high clearance compound ($E > 0.75$), Cl_{hep} predicted from parallel tube model yields a higher value than that from a well-stirred model. Hence, it is prudent to take into consideration the nature of the model with high clearance compounds. Once the predicted Cl_{hep} is calculated, the values can be expressed as percentage hepatic blood flow to classify compounds as low ($< 25\%$, Q_h), moderate ($25\text{--}75\%$, Q_h), and high ($> 75\%$, Q_h) Cl. With the recent surge of knowledge in transporters, the traditional Cl_{hep} equation has been modified to incorporate the transporter contribution to total hepatic clearance (Eq. 5, Fig. 1.8).

In early stages of drug discovery, metabolite identification is routinely performed in liver subcellular fractions, cDNA-expressed enzymes, or hepatocytes. Indeed, the results of a recent study suggested that all these systems reliably predicted human excretory and circulating metabolite profiles [88]. Although it is highly preferable to maintain low NCE concentration ($1\text{ }\mu\text{M}$) in incubation mixture to mimic physiologically relevant conditions, analytical difficulties in detection of metabolites that are formed in low quantities force most metabolite identification reactions to be performed around $10\text{ }\mu\text{M}$ or higher (depending on the extent of metabolism of the NCEs). At supraphysiological incubation conditions of most met Identification (ID) studies, the biotransformation pathways can sometimes be different from *in vivo* situation. In majority cases, this difference is mostly quantitative rather than qualitative—in other words,

Calculation of Cl_{int}

$$Cl_{int} = \frac{0.693}{in\ vitro\ T_{1/2}} * \frac{mL\ incubation}{mg\ microsomes} * \frac{45\ mg\ microsomes}{gm\ liver} * \frac{X\ gm\ liver}{kg\ BW} \quad (1)$$

$X = 20(\text{human}); 25(\text{dog, Pig}); 30(\text{Cyno}); 45(\text{Guinea pig, rat}); 87.5(\text{Mouse})$

$$Cl_{int} = \frac{V_{max} [S]}{K_m + [S]} \text{ at } S \ll K_m, \text{ simplifies to } Cl_{int} = \frac{V_{max}}{K_m}$$

(Involvement of one enzymes)

$$Cl_{int} = \frac{V_{max1} [S]}{K_{m1} + [S]} + \frac{V_{max2} [S]}{K_{m2} + [S]} \text{ at } S \ll K_m, \text{ simplifies to } Cl_{int} = \frac{V_{max1}}{K_{m1}} + \frac{V_{max2}}{K_{m2}} \quad (2)$$

involvement of two enzymes

Calculation of Cl_{hep} via Well-stirred model

$$Cl_{hep} = \frac{Q_h Cl_{int}}{Q_h + Cl_{int}} \quad (3)$$

(No protein binding)

$$Cl_{hep} = \frac{Q_h \left(\frac{1}{B/P} \right) (f_{u,serum}/f_{u,microsome}) Cl_{int}}{Q_h + \left(\frac{1}{B/P} \right) (f_{u,serum}/f_{u,microsome}) Cl_{int}} \quad (3)$$

(Plasma and microsome protein binding and blood:plasma partitioning)

$$Cl_{hep} = \frac{Q_h f_{u,blood} (Cl_{int}/f_{u,microsome})}{Q_h + f_{u,blood} (Cl_{int}/f_{u,microsome})} \quad (3)$$

(Blood and microsome protein binding)

Equation for extraction ratio

$$E = \frac{f_{u,plasma} Cl_{int}}{Q_h + f_{u,plasma} Cl_{int}} \quad (4)$$

$$E = \frac{f_{u,plasma} Cl_{influx} Cl_{int}}{Q_h Cl_{efflux} + Cl_{int} (Q_h + f_{u,plasma} Cl_{influx})} \quad (4)$$

Incorporating transporters

Calculation of Cl_{hep} incorporating transporters

$$Cl_{hep} = \frac{Q_h f_{u,plasma} Cl_{influx} (Cl_{int,sec} + Cl_{int,met})}{Q_h (Cl_{efflux} + Cl_{int,sec} + Cl_{int,met}) + f_{u,plasma} Cl_{influx} (Cl_{int,sec} + Cl_{int,met})} \quad (5)$$

Cl_{int} = intrinsic clearance

Cl_{hep} = hepatic clearance

$[S]$ = substrate concentration

V_{max} = maximum reaction velocity

K_m = substrate concentration that results in half of maximum velocity

Q_h = hepatic blood flow

$f_{u,blood/serum/plasma}$ = fraction unbound in blood/serum/plasma

B/P = blood:plasma partition ratio

Cl_{influx} = intrinsic clearance of influx

$Cl_{int,sec}$ = intrinsic clearance of biliary secretion

$Cl_{int,met}$ = intrinsic clearance of metabolism

Cl_{efflux} = intrinsic clearance of efflux

Figure 1.8 Methods to calculate Cl_{int} and Cl_{hep} .

even at artificially higher NCE concentrations, commonly used for met ID studies, the profile of metabolites would not alter significantly (in most cases), although their relative amounts and the enzymes involved in their formation may vary significantly. Very sensitive analytical LC/MS/MS- or LC/NMR-based methods have revolutionized for metabolite identification, quantitation, and characterization [89–97].

1.5.2.4 Reactive Intermediate Trapping. Reactive metabolites such as electrophilic intermediates or radicals are unstable, usually formed in small amounts, and rapidly react with nucleophiles and can, therefore, easily be missed in routine metabolism studies. Hard electrophiles react with basic groups in DNA and lysine residues in proteins (“hard nucleophiles”), while soft electrophiles react with the thiol groups of GSH and cysteine residue in proteins (“soft nucleophiles”). Radicals do not covalently bind to proteins but abstract a hydrogen atom from macromolecules. Direct detection of these reactive intermediates has proven almost impossible both *in vitro* and *in vivo* due to their inherent reactive nature. The basic methods to trap the reactive intermediates have been well established and have been used for screening of new chemical entities in a high throughput manner in early drug discovery. Majority of reactive metabolites generated are “soft” and are trapped by the endogenous thiol GSH and *N*-acetyl cysteine, while the “hard” electrophiles are trapped by the hard nucleophiles such as cyanide, methoxylamine, and semicarbazide. The trapped adducts are detected and identified by LC/MS/MS and Nuclear Magnetic Resonance (NMR).

In addition to commonly used GSH and Cyanide (CN) trapping of reactive intermediates, some of the recently emerging methods to measure “biochemical markers” of toxicity, resulting from reactive intermediate formation is also gaining popularity [98]. For example, increase in alanine transaminase level as an indicator of hepatotoxicity, induction of GSH transferase and quinone reductase as indicators of cells stress, and measure of mitochondrial function for cell toxicity have been proposed as methods that could be used for risk assessment toward reactive metabolite-mediated IDRs. Use of gene chips to explore gene expression patterns to identify individuals susceptible to IDRs has also been proposed. However, as with other existing methods, quantitative risk assessment and its clinical relevance remains a challenging hurdle for all these methods. Covalent binding assessment has also been extensively used as the gold standard for reactive intermediate screening [99]. However, expert opinion in this area emphasizes that the *in vitro* covalently binding studies are best used to *retrospectively* investigate mechanism of toxicity when encountered in clinical setting and is valuable in identifying imminent bioactivation pathways of NCEs and rank ordering NCEs in discovery stages. However, efforts to quantitatively link the degree of covalent binding to clinical toxicity should not be attempted *prospectively* [7,100–102].

1.5.2.5 CYP Identification/Mapping. In early discovery phases, a qualitative idea of the major route of elimination contributing to the total clearance of an NCE is sufficient. To tease out contribution of FMO- and CYP-mediated metabolism, it is common to incubate microsomes at 50°C for 2–3 min, as FMOs, but not CYPs, are thermally labile enzymes which can be denatured by incubating the reaction mixture in the absence of NADPH at 50°C.

During the late discovery stage, a little more rigorous method called *enzyme mapping* is implemented. Enzyme mapping helps identify the DMEs that are responsible for the overall clearance of an NCE. In early discovery stages, mapping is most commonly

done via the use of commercially available recombinant human enzymes (CYP, UGT, FMO, and NAT). Major caveat of this method is that since recombinant enzymes do not accurately represent physiological expression and specific activities of the enzymes, the results observed in recombinant enzymes are unable to give relative contribution of an enzyme to the total metabolism of the NCE *in vivo*.

When NCE is moved further into late stage discovery or early development, a more rigorous CYP phenotyping is performed where a more quantitative estimation of contribution by a CYP isoform to total NCE clearance is evaluated via a stepwise integrated approach [7,34,103].

- Step 1.* Assessment of metabolite formation of an NCE in a pooled Human liver microsomes (HLM) (20–50 donors to reduce intersubject variability) and ruling out non-CYP-mediated pathways.
- Step 2.* Enzyme kinetic parameters $V_{\max}$ and K_m for each major biotransformation pathway are determined under linear conditions (time and protein) and careful analysis of resulting Eadie–Hofstee plots (rule out multiple CYPs).
- Step 3.* Effect of CYP-isoform-specific chemical inhibitors on the particular biotransformation pathway (in HLM) is assessed (with $[S] \leq K_m$ of the NCE and $[I]/K_i > 10$ of the CYP-specific inhibitor).
- Step 4.* CYP-isoform-specific inhibitory antibodies are also used to evaluate relative contribution of different CYP isoforms toward NCE metabolism to complement data from chemical inhibitors (step 3).
- Step 5.* Relative activity factor method or intersystem extrapolation factor method are also utilized to gain an insight into relative contribution of the CYPs.

Sometimes other methods, such as, total normalized rate method, correlation analysis, or use of genotyped liver (in case where polymorphic enzymes are involved) have all been reported [34,103].

1.5.2.6 CYP Inhibition. Inhibitory potential of an NCE is routinely determined in early compound optimization stages by a simple, model-independent, IC_{50} determination assay in liver microsomes or cDNA-expressed protein [104,105]. Use of liver microsomes is more common in the case of CYPs which have specific/highly selective probe substrates and inhibitors available, while use of cDNA-expressed enzyme is more common in the case of UGT, NAT, SULT, and GST, for which isoform-specific/selective substrates and inhibitors are not well established and/or validated. Use of human hepatocytes-plasma system to predict inhibition-based DDI has also been demonstrated [106]. IC_{50} determination, in *in vitro* assays, is usually performed at one substrate concentration ($S \leq K_m$), and a wide range of inhibitor concentrations to monitor the decrease in reaction velocity with increasing inhibitor concentration. An NCE is classified as potentially high, medium, or low DDI risk based on whether its IC_{50} value for a particular enzyme is <0.1 , $0.1-1$, or $>1.0 \mu M$, respectively. IC_{50} values should be compared to maximum predicted NCE plasma concentration ($C_{\max}$) at steady state and only if IC_{50} values are greater than $C_{\max}$, a potential DDI risk *in vivo* can be anticipated. Drawback from risk prediction based on IC_{50} values is that IC_{50} values are heavily dependent on assay-dependent parameters such as the nature of sub-cellular fraction (pooled microsomes, cDNA-expressing microsomes, and hepatocytes); concentrations of the substrate, inhibitor, and enzyme; incubation time; solvent effect;

choice of marker substrate used especially for CYP3A4 and 2C9; solubility limit of inhibitor and substrate; and extent of protein binding of inhibitor.

A more rigorous assessment of inhibitor potency, usually performed for late stage discovery compounds, is via determination of K_i , which requires thorough kinetic analysis of a specific biotransformation pathway of interest. Eadie–Hoftsee (or Lineweaver–Burke) plots are generated using multiple substrate and inhibitor concentrations and the mechanism of inhibition (competitive, noncompetitive, uncompetitive, or mixed) is assigned based on model-fit of the data, defined by statistical criteria. K_i value, which unlike the IC_{50} value, is a more intrinsic number, is substrate independent, and yields a superior ranking method than IC_{50} determination. Evaluating an NCE's inhibitory potential involves assessment of its $[I]/K_i$ ratio, where $[I]$ represents the mean C_{max} (peak plasma) of inhibitor at steady state, after highest proposed clinical dose and K_i is the dissociation constant of the enzyme–inhibitor complex. An inhibition is considered high, medium, or low risk based on whether its $[I]/K_i$ ratio is >1 , $0.1–1$, or <0.1 , respectively.

1.5.2.7 CYP Induction. Reporter gene assays, such as the PXR–nuclear receptor binding assay and PXR-transactivation assay are rapid and high throughput assays are used to evaluate an NCE's potential for CYP induction. Induction has also been studied in other human hepatocytes cell lines such as HepG2, Fa2N-4, BC2, HepaRG, human intestinal cell line LS174T, and breast cancer cell line MCF-7 [79]. Each of these cell lines have their limitations, which need to be thoroughly considered before using these cell lines for predicting enzyme induction. Primary SCHHs model is deemed as the “gold standard” by DMPK scientists. Under optimal experimental/culture conditions, primary human hepatocytes maintain physiologically relevant receptors, DMEs, and transporters, all under their regulatory control and hence is a very good model to concurrently evaluate metabolism, inhibition, and induction. It has been observed that induction results obtained with primary hepatocytes cultures correlate well with clinical results. Readers are advised to refer to these excellent reviews that discuss in detail *in vitro* methodologies and optimization of experimental conditions such as culture format, number of donors, culture medium, confluence number, culture period, and so on, for studying enzyme induction with primary cultured hepatocytes. Endpoint readout in induction studies usually involves a combination of measuring the mRNA levels or protein levels or activity of the target enzyme(s) [36,107,108].

Frequently, in early discovery stages, a simple rank order approach based on C_{max}/EC_{50} ratio (C_{max} , maximum plasma concentration of inducer after administration of the highest anticipated clinical dose; EC_{50} , concentration of inducer where 50% of maximal induction is observed) is used. A high, medium, or low risk is associated to whether the C_{max}/EC_{50} ratios are >1 , $0.1–1$, or <0.1 , respectively. A more reliable method, called the *relative induction score* (RIS) method is also used to better predict clinical DDI based on *in vitro* induction data (Fig. 1.9) [108]. RIS takes into account the maximum induction response in addition to C_{max} and EC_{50} . The RIS method has also been modified to incorporate an additional No adverse effect level (NOAEL) term (Fig. 1.9), which is the highest concentration at which no induction is observed for an NCE. Generally, the DDI guidance by FDA recommends that NCEs that increase a particular isoform's enzyme activity by 40% of the positive control should be regarded as an inducer for that particular enzyme (assay done in freshly isolated or attachable cryopreserved hepatocytes in *in vitro* systems from at least three human donors).

Relative induction score	$E_{\max}$ = Maximim induction response
$\frac{E_{\max} \cdot C_{\max}}{EC_{50} + C_{\max}} = \text{Effect}$	EC_{50} = Inducer concentration that yields half maximum induction response
	$C_{\max}$ = Maximum un bound plasma concentration of inducer
	$f_{u, \text{plasma}}$ = Fraction unbound of inducer in plasma
$\frac{E_{\max} \cdot C_{\max} \cdot f_{u, \text{plasma}}}{EC_{50} + C_{\max} \cdot f_{u, \text{plasma}}} \times \frac{NOEL}{C_{\max} \cdot f_{u, \text{plasma}}} = \text{Effect}$	$NOEL$ = No adverse effect level

Figure 1.9 Calculation of RIS.

1.5.2.8 DDI Prediction in Transgenic Mice. There has been a significant recent interest in the use of genetically modified mouse models to assess DDI potential and toxicity prediction [109]. Double transgenic mouse (expressing human CYP3A4/PXR, CYPs 3A4/2D6, and OATP1B1), knockout (KO) mouse (specific drug disposition enzyme- and transporter-null mouse and SOD2 null mouse), humanized mouse (mouse expressing human CYPs PXR and PPAR), chimeric mouse with humanized liver have truly revolutionized ways to investigate the mechanism of human-specific biotransformation and toxicity [7]. However, *quantitative* prediction of clinical DDI and toxicity in human from these models is yet to be thoroughly established.

1.5.2.9 Plasma Protein Binding. The “gold standard” methods for PPB are equilibrium dialysis, ultrafiltration, and ultracentrifugation [110–112].

1.5.2.9.1 Equilibrium Dialysis. Its simple setup involves two chambers, usually plasma and buffer, separated by a dialysis membrane (MW cutoff) and an NCE (known volume and concentration) is introduced in the plasma chamber. Equilibrium between the two chambers is allowed to establish, whereby concentration of *free* NCE should be same across both sides of the membrane via simple diffusion. Quantitation of an NCE in the buffer side and the plasma side gives an estimate of percentage free NCE. This generates rapid, accurate, and quantitative data, with simple experimental setup. Caution should be exercised to minimize high membrane binding, volume shift due to osmosis, and Gibbs–Donnan effects.

1.5.2.9.2 Ultrafiltration. The assay principle is to separate a small volume of protein-free phase from plasma, containing known NCE concentration, by filtration through a semi-permeable membrane, and measure the concentration of unbound NCE in the filtrate. Also it provides the rapid, accurate, and quantitative data with simple experimental setup. Attention should be paid to membrane binding, sieve effects, Gibbs–Donnan effects, along with temperature and pH control.

1.5.2.9.3 Ultracentrifugation. This method involves application of a high centrifuge force ($100,000 \times g$ or more) to a drug solution (no membrane is required) for a prolonged period (e.g., 15 h) to sediment the protein to the bottom of the tube. The unbound drug concentration in the protein-free supernatant is measured. Although this technique is devoid of membrane-related issues or change in total drug concentration, sedimentation of drug molecules, floating lipid layer, extensive experimental setup and time, along with the need to control temperature and pH may pose as hurdles.

1.5.2.9.4 Ex Vivo PPB. *Ex vivo* PPB refers to PPB determination of a compound, via conventional PPB methods, in blood samples obtained after dosing the animals or individuals with the compound (most of the time, done with [^{14}C]-labeled compound). *Ex vivo* PPB values have been shown to yield slightly higher values than *in vitro* PPB determination [113] as reported for celecoxib. It is desirable to evaluate *ex vivo* PPB, especially in cases where a compound yields significant amount of metabolite *in vivo*. Metabolites, due to their more polar nature than the parent drug, are usually less plasma protein bound than the parent drug but an *ex vivo* evaluation in these cases captures any interaction between drug and metabolites at physiologically relevant concentration/therapeutic doses.

1.5.3 In Vivo

1.5.3.1 Absorption. OBA is defined as the fraction of drug that reaches systemic circulation after oral administration of a drug. It is therefore heavily dependent on how efficiently the drug is absorbed after an oral dose. For orally administered drugs, fraction of dose absorbed systemically F (also defined as *OBA*) is dependent on the fraction absorbed F_a , fraction escaping gut metabolism, F_g , and fraction escaping hepatic metabolism, F_h , given by the following equation:

$$F = F_a \times F_g \times F_h$$

Knowledge of fraction of dose absorbed is very informative for orally administered drugs. Although very accurate information about fraction of dose absorbed is obtained with radiolabeled compounds, yet availability of radiolabeled compound is very limited in early discovery stages and simple mechanistic studies with unlabeled compounds gives a reasonable estimate of this parameter [11,114]. For example, comparison of dose-normalized AUC between oral and intraportal vein dosing gives a reasonable estimate of $F_a \times F_g$, fraction of dose absorbed into portal vein, after an oral dosing (assuming hepatic clearance remains same between the two routes of dosing). $F_a \times F_g$ can also be estimated after oral dosing of a compound and comparison of compound concentration (dose-normalized AUCs) in portal vein versus systemic circulation. Fraction of dose escaping hepatic metabolism F_h can be estimated from either comparing dose-normalized AUCs after intraportal and intravenous (IV) dosing or after an oral administration comparing compound exposure in portal vein versus in systemic circulation (portal vein vs mesenteric artery).

KO and mutation of transporter expression in rodents is a widely used strategy to understand involvement of the silenced or mutated transporters in drug disposition in humans [115] and to explain transporter-mediated toxicity to certain xenobiotics. For example, studies in *Npc1l1*-null mice revealed the essential role of this transporter in cholesterol uptake across intestines, while *Dmt 1*-mutated rats showed that this is an important transporter for intestinal absorption of iron. Other KO models have also been valuable in investigating role of OAT, OCT, MRP2, MRP3, MRP6, ABCA1, BCRP, MDR1, MDR2, and MDR3 in hepatobiliary, renal, and brain disposition and toxicity of xenobiotics. Concurrent double and triple-transporter gene KO mice, such as *Mdr1a/b/Mrp2* KO [116], *Bsep/Mdr1a/Mdr1b* KO [115], and *Mdr1a/Mdr1b* KO [117,118], have also been very useful in understanding the role of multiple transporters in drug disposition.

Metabolite identification of *in vivo* samples is usually done in biological matrices such as plasma, urine, bile, and feces. Ion suppression from a variety of endogenous compounds in the biological matrices is a commonly encountered hurdle in *in vivo* metabolite identification and leads to drastic decrease in MS signal intensity of parent and its metabolites. A strong expertise in sample preparation and novel sample introduction into the LC/MS/MS [e.g., Ultra Performance Liquid Chromatography (UPLC) and nano-flow techniques] tremendously improves success in detection and identification of *in vivo* metabolites. There are a multitude of very good articles discussing several of these modern analytical strategies involved in metabolite identification and are highly recommended for further reading [89–97].

1.6 ADME STUDIES IN DRUG DEVELOPMENT

As described in Section 1.5, most of the ADME studies in drug discovery are conducted using cold material. However, ADME studies in drug development are generally conducted using radiolabeled (^3H or ^{14}C) material [119]. The use of radiolabeled material offers a unique mode of quantification of total drug-related molecules.

1.6.1 Absorption

Determination of the amount of drug-related material absorbed proves to be quite cumbersome using unlabeled compound. The use of a radiotracer allows an accurate quantitation of drug and drug-related material that is absorbed and this technique has been employed in studying absorption for several years. The radiolabeled version of the drug is administered orally and intravenously to intact or bile-duct cannulated animals and humans. Urine, bile, plasma, and feces are collected for as long as is necessary to obtain a full recovery of radioactivity [120]. Several methods have been then used to determine the fraction absorbed (F_a).

1. Calculating the percentage of cumulative excretion of radioactive drug-related material in urine and bile from bile-duct animals following oral administration as

$$\text{Absorption}(F_a) = \frac{\% \text{total dose excreted in urine and bile}}{100}$$

2. Measuring the amount of unchanged drug in feces after oral administration from intact animals using as

$$\text{Absorption}(F_a) = 1 - \frac{\% \text{dose of parent drug excreted in feces}}{100}$$

3. Comparing the amounts of total radioactivity excreted in the urine after oral and IV dose as

$$\text{Absorption}(F_a) = \frac{\% \text{dose excreted in urine after PO dose}}{\% \text{dose excreted in urine after IV dose}}$$

4. Comparing the exposure (AUC) of total radioactivity after oral and IV dose as:

$$\text{Absorption}(F_a) = \frac{\text{AUC}_{\text{total radioactivity after PO dose}}}{\text{AUC}_{\text{total radioactivity after IV dose}}} \times \frac{\text{dose IV}}{\text{dose PO}}$$

The extent of absorption of lasofoxifene was investigated in the intact and bile-duct rats after oral administration of single dose of [^{14}C]lasofoxifene [121]. The cumulative excretion amounted to 1.72% in the urine and 95.0% in the feces of intact rats. While in a separate bile-duct cannulated study in rats, 83% of the administered radioactivity was excreted in the bile following oral administration of a single dose of [^{14}C]lasofoxifene. These data suggest that at least 85% of dose (percentage recovery in urine and bile) was absorbed and that the fecal excretion in intact animals likely reflects excretion in the bile rather than incomplete absorption.

Barbhaiya *et al.* [122] and Shukla *et al.* [123] have demonstrated the differences in the extent of absorption of drug-related material and the systemic bioavailability of nefazodone in humans and dogs after oral and IV administration of [^{14}C]nefazodone. Plasma was analyzed for nefazodone and its metabolites, and plasma, urine, and feces were analyzed for total radioactivity. The bioavailability of nefazodone was estimated to be 14% and 15% in dogs [123] and humans [122], respectively (Table 1.3). The recovery of total radioactivity in urine and feces was similar after Oral (route of dosing) PO and IV administration for both dogs and humans, indicating complete absorption of the drug after oral administration (Table 1.3). The low bioavailability of nefazodone was due to first-pass metabolism rather than poor absorption.

1.6.2 Distribution

Drug regulatory agencies require that tissue distribution studies should be conducted with laboratory animals (rats) as a prerequisite for projecting tissue exposure to radioactivity before administration of radioactive drugs to humans. The objectives of this study are to determine the radioactivity in each organ of interest after administering the radiolabeled drug to animals. The concentration of drug-related material (total radioactivity) is determined by whole body autoradiography/whole body autoradioluminography (WBAL) or liquid scintillation counting of tissues of interest.

TABLE 1.3 Mean Total Excretion of Radioactivity and Exposure (AUC) of Nefazodone in Dogs and Humans following Oral and IV Administration of [^{14}C]Nefazodone

	Analyte	Dose (mg/kg)	Route	AUC0-inf	% Dose Excreted	
					Urine	Feces
Dog	Radioactivity	10	IV	25,642	24.9	61.1
		10	Oral	23,997	27.7	59
	Nefazodone	10	IV	6023	—	—
		10	Oral	829	—	—
Human	Radioactivity	5	IV	—	51.6	20.1
		20	Oral	—	49.1	24.1
	Nefazodone	5	IV	160	—	—
		200	Oral	1327	—	—

Prakash *et al.* [121] examined tissue distribution in male and female pigmented rats (Long–Evans) using WBAL following administration of a single oral dose of [^{14}C]lasofoxifene. [^{14}C]Lasofoxifene-related radioactivity distributed rapidly in the rat with most tissues achieving maximal concentrations at 1 h. Tissue exposure was similar in male and female rats, with the greatest exposure in the uvea. The GI contents had the highest concentrations of [^{14}C]lasofoxifene radioequivalents following oral administration. Half-life of radioactivity was longest in the uvea (124 h) and shortest in the spleen (~ 3 h). Radioactivity became undetectable in some tissues by 8 h postdose. At 168-h postdose, radioactivity could only be measured in the intestinal contents and uvea. The projected human exposure to ^{14}C radioactivity is estimated by direct extrapolation from the exposure data obtained from the rat quantitative whole body autoradiography (QWBA) tissue distribution study [124–126].

1.6.3 Metabolic Profiling and Identification

In drug development, the metabolite profiles of new drug candidates are generally accomplished by mass balance and excretion studies in which radiolabeled drugs are administered to laboratory animals and humans. The biological fluids are collected, analyzed for total radioactivity, and evaluated for a quantitative profile of metabolites. Metabolite profiling of samples is generally conducted using high performance liquid chromatography coupled with mass spectrometry (HPLC-MS) and radiometric detector. Metabolite quantification is performed by measuring radioactivity in the individual peaks that are separated on HPLC, using a radiometric detector or collecting fractions followed by counting in a scintillation counter.

As an example, the metabolic fate of torcetrapib a cholesteryl ester transfer protein (CETP) inhibitor was investigated in rats, monkeys, mice, and humans following oral administration of a single dose of [^{14}C]torcetrapib [127,128]. More than 28 metabolites were identified in all species, and they were products of oxidation and conjugation pathways [127]. The metabolites identified in humans were detected at least in one preclinical species [128].

In some cases, oxidative cleavage such as N-dealkylation or hydrolysis of the ester and amide could result in splitting of a molecule into two large fragments. In these cases, it is useful to label both sides of the molecule either with one isotope at two different positions or a mixture of two radioisotopes. This strategy has been successfully used in *in vitro* studies of a GABA_A receptor partial agonist [129] and *in vivo* Absorption-metabolism-excretion (AME) studies of torcetrapib [128], ziprasidone [130,131], and gemopatrilat [132].

1.6.4 Excretion

Excretion studies in preclinical animal species used for long-term safety assessment and human volunteers with the aid of the radiolabeled drug provide the total fate of drug-related material. One of the primary objectives of these studies is to demonstrate that the administered dose is readily eliminated from the body, ideally after exerting the intended therapeutic effect. By quantitative collection of the excreta for sufficient time, it not only provides valuable information on mass balance, route, and extent of excretion of the administered radioactive dose but also provides critical information on the clearance mechanism of the drugs.

Several studies describing the procedure for determining the excretion of drugs using [^{14}C]- and [^3H]-labeled compounds have been published [128,130,131]. We have described a mass balance and excretion study of torcetrapib in rats, monkeys, and mice by oral administration of [^{14}C]torcetrapib, labeled either at the trifluoromethyl-3,4-dihydro-2*H*-quinoline moiety or at the benzylic carbon of the bis-trifluorophenyl ring [128]. The administered radioactive dose was quantitatively recovered in all species. Excretion of the radioactivity was rapid and nearly complete within 48 h after dosing. In the rats and monkeys, the majority of dose was excreted in feces, while in the mice; the dose was recovered equally in urine and feces. In the separate studies using bile-duct cannulated rats and monkeys, only <10% of the administered radioactivity was recovered in bile. This suggested that a major portion of dose excreted in the feces of rats and monkeys was mainly due to unabsorbed dose. There were no discernible gender differences in the excretion pattern of radioactivity in these species after oral administration of [^{14}C]torcetrapib [128].

1.7 SUMMARY AND FUTURE PERSPECTIVES

Drug discovery is an extremely time-consuming, expensive, and challenging process, where success is heavily dependent on very thorough understanding of chemistry and mechanism of metabolism of NCEs in humans. Unavailability of data in humans in early drug discovery stages makes it imperative to have well-validated, rapid *in vitro* ADME tools, in complement with relevant *in vivo* preclinical animal models, to accurately predict ADME/PK of an NCE in humans to minimize risk of failure in late stages of development. With advancement of technology, there is a plethora of *in silico* and *in vitro* assays available to model and evaluate each pathway of the complex ADME process such as involvement of transporters and DMEs, possible risk associated with their inhibition or induction, implications of enzyme polymorphism, insight into mechanistic biotransformation pathways, and reactive intermediate formation. It must be borne in mind that each of these *in silico* modeling techniques and *in vitro* assays and systems (e.g., recombinant enzymes, microsomes, hepatocytes, and membrane vesicles) have their limitations, depending on the experimental conditions tested (e.g., types of molecular descriptors in the case of *in silico* models and substrate concentration, buffer, incubation time, pH, and protein concentration, in the case of *in vitro* assays) and results must be carefully interpreted during ADME optimization of an NCE. Preclinical animal models should also be very carefully evaluated since there is significant species and gender difference in biotransformation pathways of NCEs, not only due to differential expression and activity of the transporters and DMEs but also in animal physiology and genetic polymorphism. Designing the correct *in vitro* and *in vivo* experiments and intuitively interpreting and integrating all ADME/PK data are challenging but key steps toward risk mitigation of an NCE in a clinical setting. More often than not, even with the most sophisticated modeling and the best designed experiments, extrapolation of animal data to human fails due to highly species-specific expression levels, tissue localization, substrate specificity and gene regulation of transporters and DMEs, and differences between human and animal physiology. To address these issues, IV microdose and pharmacologically active oral dose strategies for exploratory phase I studies should be employed.

ACKNOWLEDGMENT

The authors would like to thank Dr. Lewis Klunk for reviewing this article and providing insightful comments.

2.1 SUMMARY

The rate at which ingested compounds are absorbed into the bloodstream from the gastrointestinal (GI) tract and extent to which they are absorbed are governed by the physical–chemical properties of the ingested compounds, the presence and identity of other substances in the GI tract, and the anatomical and physiological characteristics of the GI tract. Humans and laboratory animals share the same basic blueprint for the GI tract, and this chapter describes the organs of the GI tract, the microscopic structure of the GI luminal epithelium, and the flow of blood and lymph from the GI tract. However, there is remarkable variability across species in the absorptive surface area of the GI tract, the time it takes for materials to move through the GI tract, and the nature of the GI contents. By understanding these differences among species, scientists can better predict the pharmacokinetics of a substance in a species or extrapolate pharmacokinetic data from one species to another.

2.2 INTRODUCTION

GI absorption entails the passage of materials from the lumen of GI tract (alimentary canal) to the bloodstream. Absorption of nutrients and essential minerals are crucial for a normal, healthy life. Understanding which materials are absorbed, in what specific portions of the alimentary canal, at what rate, and by what mechanisms is important to nutritionists, pharmacologists, and toxicologists. In all cases, scientists want to know how substances pass from the lumen to the bloodstream. Information about the process of absorption and factors that affect it are essential for modeling absorption kinetics and predicting the biodistribution of a substance within a given animal or extrapolating the findings between species (e.g., from rats to humans). Physiologically based pharmacokinetic models and biologically based models are valuable tools for predicting or extrapolating absorption, but they require qualitative—as well as quantitative—knowledge about the biological systems under study.

The rate and extent of absorption of orally ingested compounds are influenced by both properties that are intrinsic to the ingested substances themselves and factors that are associated with the milieu of the alimentary canal and its absorptive surface [1–4]. The most significant intrinsic factors that affect absorption are the physical and chemical properties of a substance, including its lipid solubility, ionization state, and molecular weight or size. These intrinsic factors are independent of the test species. Absorption of a substance is also extensively affected by the presence of other materials within the GI tract, including food eaten before or concomitantly with ingestion of the substance, or in the case of some experimental studies, the vehicle or solvent in which the substance is administered.

It is emphasized that the parameters discussed herein are those that influence the crossing of materials from the GI lumen into the bloodstream of the GI tract. From the major absorptive areas of the GI tract, blood passes by means of the hepatic portal system to the liver, where absorbed materials are subject to possible metabolism or storage. This process is termed the *first-pass effect* because it effectively reduces the concentration or amount of material absorbed from the GI tract that enters the systemic circulation. Thus, while information about absorption of materials from the GI tract is the first step in determining potential biological effects, this does not always provide accurate measures of concentrations found at target tissues that are distant from the GI tract [5].

The factors that contribute most to the interspecies differences in GI absorption are the anatomy and physiology of the GI tract of the species under consideration. Before discussing the differences among species, however, it is important to review their similarities.

2.3 OVERVIEW OF THE ALIMENTARY CANAL

The overall organization of the GI tract of humans is comparable to those of most test species. Detailed information concerning the anatomy and physiology of the GI tract in animals and humans can be found in various sources [6–10] and has been summarized therefrom. Figure 2.1 depicts the regions of the alimentary canals for humans and rats. The alimentary canal is an open-ended tube that extends through the body from the mouth to the anus. One can envision the lumen as a tunnel of the

Figure 2.1 Alimentary canals of primates and rodents. In the primate (human depicted in panel a), note the eccentric position (left side) for the entry of the esophagus into the stomach. The portal into the small intestine is nearly horizontal. The small intestine is divided into duodenum (the short initial segment), jejunum, and ileum. The ileum empties into the large intestine. The first part of the large intestine (the cecum) has the largest diameter; the vermiform appendix is attached near its proximal end. Note that the diameter of the large intestine decreases as material traverses caudally. The rodent GI tract (rat depicted in panel b) shares the same overall organization as the human's, but with a few important differences. Note that the esophagus enters the stomach at a central location and that the entry into the duodenum faces cranially. The relative lengths of the small intestine differ from those of the human in that the jejunum makes up nearly the entire small intestine. The cecum of the rat is extremely large and lacks the presence of a vermiform appendix. Note that figures are not drawn to scale. *Source:* Reproduced from DeSesso JM, Jacobson CF. *Food Chem Toxicol* 2001;39:209–228, with permission.

external environment that runs through the body and the wall of the alimentary canal as the interface between the environment and the circulatory system [11,12]. The main functions of the alimentary canal are the digestion of food, the absorption of nutrients and other substances, and the propulsion of material through the digestive tract.

The mouth provides access to the alimentary canal. There, ingested materials are crushed and mixed with saliva by chewing (mastication). While enzymes found in saliva initiate the breakdown of carbohydrates and fats, saliva importantly acts as a lubricant for the ingested material. When a bolus of masticated material attains an appropriate consistency, it is propelled by swallowing (deglutition) into the pharynx.

The pharynx is a conduit that is shared by the respiratory and digestive systems. In humans, the pharynx has an extensive anterior opening that connects to the nasal cavity and mouth in its upper half; inferiorly, the pharynx connects to the esophagus and larynx. For the purposes of this discussion, *pharynx* refers only to the combined oral and laryngeal regions because under normal conditions, the nasopharynx does not participate in ingestion or swallowing. In the rat, mouse, and rabbit, the pharynx is divided into a respiratory region (an elongated nasopharynx) and a digestive region (analogous to the human's laryngopharynx). There is no oropharynx in these species

because the epiglottis rests against the palate and separates the nasal cavity from the oral cavity (see Ref. 13 for a comparison of the oral and upper respiratory regions of rats and primates). The inferior end of the pharynx adjoins the esophagus, a hollow muscular tube capable of considerable expansion. Little digestion or absorption occurs in the pharynx and esophagus; rather, these structures serve to rapidly transfer ingested material from the mouth to the stomach.

The stomach is a capacious muscular organ that mixes the ingested material with additional secretions to facilitate digestion. The stomach of rodents and lagomorphs has two grossly discernible regions: the forestomach and glandular stomach. The two are separated by a limiting ridge, which prevents these species from vomiting (Fig. 2.2a). The forestomachs of rodents and lagomorphs serve as an entry from the esophagus and are lined by stratified epithelium. The forestomach of rats and mice (but not rabbits) contains numerous bacteria that are important in their digestive processes. The epithelium that makes up the forestomach surface in these species resembles the

Figure 2.2 Interior structures of rodent and primate stomachs. The interior of the rat stomach (a) exhibits two distinctive regions separated by a prominent limiting ridge, which precludes the rat from vomiting. Food enters the stomach at the forestomach, a nonsecretory region with a hardy epithelium. The portion of the stomach that exits to the duodenum is the glandular stomach, which is lined by a delicate secretory epithelium and exhibits prominent folds (rugae) that are noticeable when the stomach is empty. Entry of food into the duodenum is regulated by a prominent muscular sphincter, the pylorus. The human stomach (b) differs from that of the rat in that the entire lining is secretory and there is no forestomach or limiting ridge. The human stomach has numerous rugae. *Source:* Reproduced from DeSesso JM, Jacobson CF. Food Chem Toxicol 2001;39:209–228, with permission.

mucous membrane of the oral cavity. The other portion of the stomach, the glandular region, contains acid-secreting glands. In dogs, pigs, and primates (including humans), the stomach is a single chamber that is secretory in nature and contains mucus- and acid-secreting cells. The human condition is depicted in Fig. 2.2b. The predominant gastric secretion in all species considered herein is rich in hydrochloric acid. In humans, the daily volume of gastric secretions can reach 1.5–2 L [4]. Gastric secretions act to continue the disintegration of food particles and to denature proteins. After mixing in the stomach for as many as several hours, small boli of the ingested material (now termed *chyme*) pass through the pyloric sphincter to the small intestine, where digestion is essentially completed and the majority of absorption takes place.

The small intestine is the major site for absorption of nutrients, water, electrolytes, and xenobiotics. The small intestine exhibits three unequally sized portions: the duodenum, the jejunum, and the ileum. These sections differ in length from species to species. The proximal part of the small intestine, the duodenum, receives secretions from numerous sources, including

- the pancreas—high in volume and rich in digestive enzymes and bicarbonate,
- the liver—bile (discussed in Section 2.7.2), and
- enteric (Brunner's) glands, located in the wall of the small intestine—rich in bicarbonate that neutralizes acid from the stomach.

The volume of these secretions in primates, dogs, and pigs more than doubles that from the salivary glands and stomach and serves to make the chyme watery. In contrast, the chyme of rodents remains rather pasty [4]. In humans, the majority of absorption occurs in the duodenum and the proximal half in the jejunum. In rodents and lagomorphs, absorption occurs more uniformly along the duodenum and entire jejunum. At the distal end of the ileum, chyme passes into the large intestine.

In primates, the large intestine is divided into the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anal canal. The other species discussed herein have similar divisions, except that, because of the absence of a true pelvis, they do not have a region designated as the sigmoid colon. The first portion of the large intestine, the cecum, has disparate functions among various species. In primates, fluids and salts that remain after completion of intestinal digestion are absorbed in the cecum. Rabbits, which are herbivores, have a much larger cecum that contains large amounts of bacteria that help digest cellulose. The ceca of carnivores such as dogs use strong muscle contractions to reverse the propulsion of the chyme and bring it back from the more distal regions of the large intestine to mix with newly arrived chyme from the ileum. As the chyme moves through the cecum and the remainder of the colon, it is mixed with intestinal bacterial flora. In fact, most nutrient processing in the large intestine is due to bacteria; little processing occurs as the result of intestinal mucosal/secretory activity. Substances formed as a result of bacterial metabolism that have properties favorable for absorption may be taken up from the large intestine. Water and electrolytes also continue to be absorbed from the large intestine. The progressive absorption of water from the chyme–bacterial matrix results in the formation of solid feces, which are eventually propelled to the rectum and stored until expulsion during defecation.

2.3.1 The Nature of the Protective and Absorptive Interfaces

Histologically, the GI tracts of humans and most test species are quite similar [14]. Detailed descriptions of the luminal surface of the alimentary canal can be found in textbooks of histology [15–17] and in various reviews [2,4,18]. Briefly, the alimentary canal is lined from the mouth to the anus with a mucosa that functions as the first barrier to entry of materials from the GI tract into the body. The mucosa is composed of an epithelium that is superimposed over a thin layer of loose connective tissue (lamina propria) in which reside blood capillaries and lymphatic vessels. The epithelial cells of the mucosa (discussed in further detail below) are joined together by tight junctions throughout the alimentary canal. The regions of the alimentary canal can be categorized by function: conduits that propel ingested substances through the canal (mouth, pharynx, esophagus, lower rectum, and anus) and regions that operate in digestion and absorption (stomach, small intestine, and all but the distal large intestine).

The mucosae of the conduits are usually a moist, stratified squamous epithelium (five to seven layers of cells) with a poorly vascularized lamina propria. In some conduit regions that are subjected to physical stress (such as the mouth), the epithelium may be keratinized. Conduit regions generally exhibit flat luminal surfaces with few irregularities that would increase the mucosal surface area. The mucosae of conduit regions are not well adapted for absorption due to their multiple layers of epithelial cells, reduced surface areas, and relatively sparse vascularization.

The mucosae of the absorptive regions differ markedly from those of the alimentary conduits. Absorptive mucosae exhibit simple columnar epithelium (i.e., a single cell layer) with prominent, well-vascularized laminae propriae. The mucosa in the absorptive regions of the alimentary canal is further characterized by modifications of the mucous membrane that increase the absorptive surface area (Fig. 2.3). These modifications include (i) large folds of the mucosal membrane (*plicae circulares*, also known as *valves of Kerckring*) that are present in some species, (ii) fingerlike projections of mucosal membrane called villi, and (iii) numerous projections from the luminal surface of the epithelial cell membrane to form a brush border (microvilli). This increased surface area of the mucosa is conducive to the transfer of substances from the lumen to the vascular system.¹

While the epithelia of the absorptive regions include diverse cell types, the predominant cell type important in the process of absorption is the enterocyte (Fig. 2.4). As previously noted, enterocytes are columnar epithelial cells that are joined to adjacent cells at the luminal surface by tight junctions. Absorption usually requires passage through the epithelium, the lamina propria, and the walls of blood or lymph capillaries. There are certain normal conditions that allow substances to traverse the junctions between epithelial cells [19–21]. Further, this process can be exacerbated in some disease states, for example, cholera [22]. The apical cell membrane of an enterocyte from the small intestine possesses an estimated 3000–7000 microvilli, which greatly increase the surface area available for absorption [11,23]. There are fewer microvilli on

¹The mucosa of the esophagus forms longitudinal folds and the wall of the stomach has ridges (*rugae*); however, these surface modifications serve to allow expansion during swallowing and after a meal, respectively, rather than increase absorption. Also, some epithelial cells in the stomach have microvilli, although these are secretory in function rather than absorptive. Thus, the surface modifications in the esophagus and stomach do not increase the *absorptive* surface area.

Figure 2.3 Cross sections of proximal small intestines of primates and rodents. Luminal surface modifications in (a) human and (b) rat. The surface areas for absorption from the lumina of the small intestines of rats and humans are greatly increased by the presence of millions of tiny fingerlike projections (villi). In the rat (b), which has a thick, chalky chyme, the villi project into the lumen from the cylindrical intestinal wall. In humans (a), who have a watery chyme, the absorptive surface area is further amplified by the presence of folds of luminal epithelium (plicae circulares) that intrude into the lumen, thereby allowing many million more villi to come into contact with chyme. (See also Fig. 2.7 to appreciate the difference in blood supplies to areas with many vs few intestinal folds.) *Source:* Reproduced from DeSesso JM, Jacobson CF. *Food Chem Toxicol* 2001;39:209–228, with permission.

enterocytes of the large intestine. Absorptive epithelial cells rest on a basement membrane and possess a carbohydrate-rich glycocalyx coat on the surface of the microvilli.

The lamina propria in absorptive regions of the alimentary canal possesses a rich supply of blood capillaries and lymphatic vessels. When villi are present (Fig. 2.5), the vascularized lamina propria makes up the core of each villus. The dilated, blind-ending lymphatic capillaries occupy the center of the villus; the blood capillaries form a meshwork of vessels beneath the basement membrane. Absorption may be augmented where fenestrations (small holes) in the capillary endothelial cells or pores in enterocyte membranes are found.

In some absorptive regions of the alimentary canal, such as the small intestine, a thin layer of smooth muscle, muscularis mucosae, lies within the lamina propria of the mucosa. Contractions of the muscularis mucosae appear to assist in the rhythmic movements of the villi that agitate the layer of intestinal secretions and chyme that are in contact with the epithelium (the unstirred layer) and thus promoting absorption.

Figure 2.4 A typical intestinal epithelial cell (enterocyte). Enterocytes are high cuboidal to low columnar epithelial cells that rest on a basal lamina. Enterocytes are joined firmly to adjacent cells by tight junctions. The nucleus occupies the basal portion of the cell. The apical surface exhibits numerous microscopic projections (microvilli) that project into the lumen and give the appearance of a “brush border” when seen with a light microscope. Microvilli greatly increase the available absorptive surface area for the enterocyte. Nearly all substances taken up from the intestinal lumen traverse the cytoplasm of an enterocyte. Lipids and fats are absorbed at the base of the microvilli, traverse the cytoplasm, and exit the enterocyte at its lateral aspect, beneath the tight junctions. In contrast, amino acids, triglycerides, and carbohydrates are absorbed throughout the length of the microvillus. These substances traverse the cytoplasm and exit the enterocyte at its base. Under certain conditions, solvent drag (or convection) can be a paracellular route that takes advantage of partial separations of the tight junctions between intestinal cells to allow the passage of large amounts of water and small solutes. *Source:* Reproduced from DeSesso JM, Jacobson CF. *Food Chem Toxicol* 2001;39:209–228, with permission.

2.3.2 Sites of and Barriers to Absorption

Throughout the length of the alimentary canal, the luminal epithelium is both a barrier to the entry of undesirable luminal contents (such as bacteria and undigested materials such as cellulose) and a facilitator in the absorption of advantageous substances. Detailed discussions of these topics can be found elsewhere [3,4,11,20,24]. While the systemic absorption of orally ingested materials takes place predominantly in the small and large intestines, limited absorption occurs at other sites as well. The most important nonintestinal absorption site is the stomach, which can take up nonionized, lipophilic molecules of moderate size. Compared to that of the intestines, gastric absorption is limited by the comparatively small epithelial surface area, relatively large volume, and the brief amount of time that substances are in contact with the stomach epithelium. Neither the characteristics of the oral/pharyngeal/esophageal epithelium nor the transitory time that substances are in contact with the mucosa of those regions favors absorption. A small amount

Figure 2.5 Structure of an intestinal villus. The luminal surface of the entire intestinal tract, including each villus, is lined by enterocytes. Note the fuzzy appearance of the brush border on the surface of the villus. The deep structure of the villus is characterized by a large, blind-ending lymphatic vessel (the lacteal), which absorbs higher molecular weight substances, including fats. The lacteals are tributaries to the intestinal lymphatic channels that coalesce at the cisterna chyli, the origin of the thoracic duct. Materials transported in the chyle (fatty fluid) bypass the liver and avoid the first-pass effect (see Fig. 2.10 to appreciate the route of lymphatic drainage from the GI tract). Note the small plexus of blood capillaries that surround the lacteal. In addition to the vascular structures, the villus contains loose connective tissue and small amounts of smooth muscle (muscularis mucosae). The muscularis mucosae wiggle the villi back and forth in the liquid layer of the lumen adjacent to the intestinal cells, thereby increasing the efficiency of absorption. *Source:* Reproduced from DeSesso JM, Jacobson CF. *Food Chem Toxicol* 2001;39:209–228, with permission.

of absorption occurs sublingually (at the underside of the tongue and the floor of the mouth beneath the tongue) and across the buccal membranes; these routes are exploited in the delivery of certain pharmaceuticals (e.g., nitroglycerin and isosorbide dinitrate) [25].

Mechanisms that allow for the passage of materials from the lumen to the bloodstream include (i) passive diffusion across the epithelial membrane, (ii) facilitated (carrier-mediated) diffusion, (iii) active transport, (iv) aqueous pores within the cell membranes or tight junctions, and (v) endocytosis (the transport of material into the cell by folding of the cellular plasma membrane inwards to form a vacuole). These mechanisms of transfer are localized in select portions of the alimentary canal, predominantly in the small intestine.

Most xenobiotic substances are absorbed in the intestines via diffusion across the luminal surface to gain access to the vasculature of the lamina propria. Passive diffusion follows Fick's law of diffusion [26,27]. Fick's law of diffusion states that bulk diffusion at steady state is proportional to the efficiency of exchange (membrane characteristics) and available surface area. Diffusion requires that a substance comes into intimate contact with the absorptive surface of the alimentary tract. Factors that affect passive

diffusion include the expanse of absorptive surface area and the amount of time the substance is in contact with that surface area. Thus, to be able to relate GI absorption in various animal species to humans, it is important to have an understanding of the dimensions of the absorptive regions of the alimentary canal, the available surface areas of those regions, and the transit time of ingesta through each subdivision of the alimentary tract across species. These topics are discussed in Sections 2.5 and 2.6.

2.4 VASCULARITY

The tissues of the alimentary canal are richly vascularized by both the blood and lymphatic systems. Absorbed substances that have passed through the enterocytes gain access to the interstitial fluid of the lamina propria. The interstitial fluid has two sources: fluid in chyme that leaves the lumen of the alimentary canal and an exudate of plasma derived from the capillaries in the lamina propria. The amount of plasma exudate in the lamina propria increases as a result of the physiological hyperemia that occurs when chyme is present in the alimentary tract. The blood and lymphatic vascular systems act as a sink for excess interstitial fluid: absorbed substances move from the interstitium to the vessels by Le Châtelier's principle, depending on the relative flow of fluids in the two systems and the anatomical arrangement and structure of the vascular beds (Figs. 2.6–2.8).

2.4.1 Blood Flow

The GI tract of mammals is richly supplied from three major arteries that emerge from the aorta. The major arteries vascularize the upper (stomach and duodenum), middle (jejunum, ileum, cecum, and the ascending and about half of the transverse colons), and lower (remainder of transverse and descending colons and the rectal regions) regions. Figure 2.6 is a diagram of the arterial supply to the rat intestinal tract. The human pattern is similar; textbooks of anatomy provide great detail for the human condition [10,28].

The perfusion rate for the blood vasculature is about 1000 times that of the lymphatic vasculature for most tissues [11]. Nevertheless, the resting lymph flow rate from the small intestine is measurable (~ 0.095 mL/min/100 g of intestinal tissue in humans [29]) and increases after meals. Indeed, when the intestine is absorbing at its maximum rate, the lymphatic vasculature transports about 20% of the absorbed fluid [29].

The blood capillaries are organized as a network (plexus) immediately subjacent to the basement membrane of the enterocytes. The degree of vascularity of this plexus is not constant along all regions of the GI tract (Fig. 2.7). A blood capillary comprises a single, thin endothelial cell layer and the surrounding basal lamina. The distance between the basal lamina and the capillary lumen is no more than a few micrometers. Some endothelial cells additionally have $500 \text{ \AA}$ ($0.05 \text{ }\mu\text{m}$) diameter openings (fenestrations) overlain only by the basal lamina; these fenestrations expedite absorption of water and various water-soluble materials [30]. Interestingly, the basal lamina appears to act as sieve; thus, molecules as small as albumin [$\sim 75 \text{ \AA}$ ($0.0075 \text{ }\mu\text{m}$) diameter] are excluded from absorption.

Figure 2.6 Arterial gastrointestinal supply in the rat. The rat arterial pattern is quite similar to that of the human (not shown). In both species, blood is provided by three major branches of the aorta: the celiac artery (which supplies the caudal portion of the esophagus, the stomach, the proximal duodenum, and portions of the pancreas), the superior mesenteric artery (which provides blood to portions of the pancreas, the caudal duodenum, the entire jejunum and ileum, the cecum, and the proximal half of the large intestine), and the inferior mesenteric artery (which furnishes blood to the caudal large intestine and most of the rectum). Note that the arteries enter the intestines along the margins of the organs and travel in tissue folds (mesenteries) that connect the intestines to the body wall. *Source:* Reproduced from DeSesso JM, Jacobson CF. Food Chem Toxicol 2001;39:209–228, with permission.

2.4.2 Lymphatic Flow

The lymphatic vessels are single saclike vessels (lacteals) located at the core of each villus. Their walls are made of a single endothelial cell layer, but the endothelial cells located here are thinner than blood capillary cells with no overlying basal lamina or fenestrations. Owing to apertures between adjacent endothelial cells, lymphatic vessels are permeable to even the largest chylomicrons [$\sim 6000 \text{ \AA}$ ($0.6 \text{ }\mu\text{m}$) diameter]

Figure 2.7 Blood supply in proximal versus distal small intestine. (a) Depicts the human proximal jejunum, which can be compared to (b), the distal ileum. The vascularity of these intestinal segments was visualized by injecting the superior mesenteric artery with colored gelatin, followed by clearing of the tissue in benzene. Note the much greater vascularity in the wall of the jejunum (a) versus that of the ileum (b), indicating the greater potential for jejunal absorption. This is a consequence of the presence of numerous plicae circulares in the proximal portion of the human small intestine. *Source:* Drawn after a preparation by M. C. E. Hutchinson [Warwick and Williams, 1973, p. 1285]; Reproduced from DeSesso JM, Jacobson CF. *Food Chem Toxicol* 2001;39:209–228, with permission.

emulsion droplets of resynthesized triglycerides, reesterified cholesterol, and phospholipids] [11,31].

2.4.3 Distinctions Between the Vascular Systems

The anatomical differences between the two vascular systems result in segregated routes of absorption for water-soluble materials versus chylomicrons. Water-soluble materials

Figure 2.8 Human hepatic portal system. Blood draining from the stomach (via the gastric veins) and the entire small and large intestines (via the superior and inferior mesenteric veins) enters the large hepatic portal vein, which delivers the blood to the liver before the blood returns to the heart by way of the inferior vena cava. This vascular arrangement ensures that all materials absorbed into the blood capillaries of the gastrointestinal tract pass through the capillaries/sinusoids of the liver, where materials can be removed or metabolized before entering the general circulation. This is the anatomical foundation for the phenomenon known as the *first-pass effect*. Source: Reproduced from DeSesso JM, Jacobson CF. Food Chem Toxicol 2001;39:209–228, with permission.

are taken up by the blood vascular route, whereas lipophilic substances associate with chylomicrons and, therefore, follow the lymphatic route [20,32]. Amphipathic substances exhibiting moderate lipophilicity partition between chylomicrons and the aqueous route [12,33].

While both vascular systems serve as pathways that eventually return fluid to the systemic circulation, their routes of return have important differences. Blood vasculature from the gastroenteric organs (stomach, small intestine, and most of the colon) form into veins that ultimately become the hepatic portal vein. The hepatic portal vein drains to the liver, where the blood disperses into the sinusoids of the liver and comes

into intimate contact with the liver tissue. Enzymes within the hepatocytes can biotransform xenobiotics to either more or less biologically active substances, concomitantly reducing blood levels of the parent compound. As previously noted, this phenomenon is termed the *first-pass effect*. To leave the liver, the blood follows vessels that re-coalesce into the hepatic veins, which drain into the inferior vena cava en route to the heart. Thus, water-soluble substances absorbed from the gastroenteric organs first pass through the liver before entering the systemic circulation. The venous return of the hepatic portal systems for humans and is illustrated in Figs. 2.8 and 2.9, respectively.

High molecular weight and lipophilic substances in the lymphatic fluid draining from the stomach and intestines follow the lymph channels to the saclike cisterna chyli, which is the origin of the thoracic duct (Fig. 2.10). From the thoracic duct, lymph returns to the systemic circulation at the juncture of the left subclavian and left

Figure 2.9 Rat hepatic portal system. The pattern of venous return from the gastrointestinal tract in rats exhibits some variability; therefore, for the purposes of this illustration, a common pattern of venous return is shown. In general, the venous return is similar to that of humans in that blood draining from the intestines eventually coalesces into the hepatic portal vein, which obligatorily passes through the liver before entering the inferior vena cava. Note that due to the postural difference between humans (upright) and rats (prone), the names of the analogous mesenteric veins of the rat are the cranial and caudal (rather than superior and inferior) mesenteric veins. *Source:* Reproduced from DeSesso JM, Jacobson CF. Food Chem Toxicol 2001;39:209–228, with permission.

Figure 2.10 Human thoracoabdominal lymphatic system. Some high molecular weight and fatty materials absorbed from the intestinal tract make their way into the lacteals and follow the lymphatic channels through the cisterna chyli to the thoracic duct, to eventually enter the general circulation at the point where the left internal jugular and left subclavian veins join to form the brachiocephalic vein. From this point, the blood and lymph pass directly to the right atrium of the heart. Thus, materials absorbed into the lymphatics bypass the liver and do not undergo first-pass metabolism. Rats have a similar arrangement of lymphatic vessels, and consequently, materials absorbed into the rat lymphatic system also avoid first-pass metabolism. *Source:* Reproduced from DeSesso JM, Jacobson CF. *Food Chem Toxicol* 2001;39:209–228, with permission.

internal jugular veins in the root of the neck, thereby circumventing the liver and first-pass metabolism. The first capillary bed traversed by substances that are transported from the alimentary canal into the lymphatic system is at the lungs. Interestingly, any substance (regardless of its molecular weight or lipophilicity) that is absorbed into the bloodstream from the oral cavity (i.e., sublingually or buccally) returns to the heart by way of the superior vena cava, thereby also evading first-pass metabolism.

2.5 DIMENSIONS OF REGIONS OF THE GASTROINTESTINAL TRACT

While the basic organization of the alimentary canal of all mammals is comparable, there are great disparities in the dimensions of some GI structures, including the lengths and surface areas of the various subdivisions. In addition, the “environmental” conditions (e.g., pH and fluidity of the chyme and number and type of bacterial flora) within the lumen of the various subdivisions differ greatly among species. These differences, and their comparison to the human condition, must be taken into account when selecting an animal model for drug disposition studies and when extrapolating the results of studies from animal to human.

The portions of the GI tract considered in the remainder of this document are those involved in absorption of ingested materials, including the stomach, small intestine (duodenum, jejunum, and ileum), and large intestine (cecum, ascending colon, transverse colon, descending colon, and rectum).

2.5.1 Linear Dimensions

This section concentrates on the lengths and percentages of total length of the small and large intestinal regions of the GI tract for seven species (mouse, rat, rabbit, dog, pig, monkey, and human). The data are presented in Table 2.1. The lengths for subdivisions of each region are reported, when available. The data were assembled from multiple sources and, consequently, are presented as ranges when sources disagree.

Inspection of Table 2.1 finds wide ranges in the reported lengths of various portions of the intestinal tract among species. These discrepancies may be due to variations in measurement methods as discussed by Snyder *et al.* [23] and Choi and Chiou [34]. For instance, if the investigators used intubation procedures, their measurements could be too short, either because the intestines tend to gather on the tube or because the propensity of the tube to stray from the center of the lumen by cutting corners. Post-mortem measurements may be too long because of the loss of smooth muscle tone in the intestine, which leads to flaccid intestines. If the intestines were fixed, imprecise measurements are likely due to the shrinkage that is attendant to the fixation process.

Potential artifacts notwithstanding, Table 2.1 shows that the rat cecum, which is a primary site for microbial digestion [43], makes up ~26% of the length of the large intestine, whereas the cecum accounts for only about 5% of the large intestinal length in humans. Interestingly, the rabbit has the longest cecum among the species considered herein. Rabbits are the only herbivores among the subject species. Microbial fermentation of dietary fiber occurs in the rabbit cecum and is the main source of rapidly absorbed volatile fatty acids [44]. Of the species for which data are available, none possesses intestinal length measurements that are proportional to those of the human.

2.5.2 Surface Areas

While comparison of the absolute and relative lengths of the subdivisions of the intestinal tracts reveals some interesting differences among these species, the lengths do not provide adequate information about the surface areas available for absorption. For instance, as noted by DeSesso and Jacobson [4], while the human small intestine is only about 5.5 times the length of the rat small intestine, the human surface area is more than 250 times that of the rat due to modification of the interior surface of the intestine as discussed below.

TABLE 2.1 Comparison of Lengths of the Intestinal Tract and Its Major Subdivisions in Seven Different Species

Region of Intestinal Tract	Mouse			Rat			Rabbit			Dog			Pig			Monkey			Human

The small intestinal surface area is important because the vast majority of substances that are absorbed in the GI tract do so in the small intestine, where they gain access to the bloodstream by means of passive diffusion. As noted by DeSesso and Jacobson [4], the absolute surface area of the human small intestine is more than 3800-fold greater than the surface area of the stomach. This enormous difference in surface areas helps explain why gastric absorption of substances is generally small when compared to intestinal absorption. Similarly, because of the modest surface area of the human large intestine (0.35 m^2 , which is less than 0.15% that of the small intestine), the large intestine tends to play a minor role in absorption compared with the small intestine.

Because the available surface area is a dominant factor in passive diffusion, Table 2.2 presents the smooth luminal surface areas of the small intestine for seven species, including humans. Various authors calculated smooth luminal values by conceiving of the small intestine as a cylinder and using the length and diameter measurements. As noted in Table 2.1, the values listed therein should be considered estimated measures. As previously mentioned, the rate and extent of absorption is increased by expansion of the absorptive surface area. The absorptive surfaces of the small intestine in the subject species exhibit modifications that increase the surface areas by a combined factor of 100–750 depending on the species, as shown in Table 2.2 and illustrated in Fig. 2.11.

TABLE 2.2 Calculated Total Small Intestinal Surface Areas for Seven Species

Species	Body Weights (kg)	Smooth Luminal Surface Area (m^2)	Fold-Increase Factors			Combined Multiplication Factors	Estimated Total Surface Area (m^2)
			Plicae	Villi	Microvilli		
Mouse	0.032	0.004 ^a	(1) ^b	(5) ^b	(20) ^b	100	(0.4)
Rat	0.3	0.016 ^a	1 ^c	5 ^c	20 ^c	100	1.6
Rabbit	2.6–3.9	0.087–0.096 ^a	1 ^d	5.7 ^e	24 ^f	136.8	11.9–13.1
Dog	10.7–12.6	0.099–0.14 ^{a,g}	1 ^d	10 ^h	25 ⁱ	250	24.75–35

Figure 2.11 Increases in absorptive surface area by anatomic modifications of the intestinal wall. (a) The absorptive surface area of the intestine is depicted as that of a cylinder having a nominal value of 1. Modifications that increase the surface are shown to the right. (b) Folds of mucosa (plicae circulares) are represented. In species that have plicae circulares (monkey and human, among the species considered herein), the surface area is increased approximately threefold. (c) Fingerlike villi are shown projecting from the surface of the intestinal mucosa throughout the length of the intestine. The dimensions (length and width) of the villi vary for each species, as does the number of villi per square millimeter of mucosal surface. The villi increase the absorptive surface area by 5- to 10-fold. (d) The brush border on the surface of individual enterocytes is illustrated. The brush border is composed of microvilli, which further increase the absorptive surface area by 20- to 25-fold. *Source:* Reproduced from DeSesso JM, Williams AL. *Annu Rep Med Chem* 2008;43:353–371, with permission.

The greatest increase in absorptive surface area due to these modifications occurs in humans. Among the species listed in Table 2.2, only monkeys and humans possess plicae circulares, which increase the luminal surface area approximately threefold. Intestinal villi increase the luminal surface area by a factor ranging from 5 to 10. The range in values is due to interspecies variations in the dimensions of the villi (e.g., length, width, and density of the microvilli), as well as changes in dimensions within the different regions of the small intestine [8,23]. That is, the architecture of the villi changes as one progresses distally through the intestine. For example, villi in the duodenum tend to be broader than those of the ileum [45,46], resulting in a gradient of decreased surface area as one moves distally through the small intestine [47]. This gradient is even greater in those species (monkey and human) that possess plicae circulares (which also tend to be larger and more numerous in the proximal intestine). Microvilli, which account for the brush border, further increase the absorptive surface area by a factor of 20–25.

2.5.3 Relative Surface Areas

Animals of dissimilar sizes have different basal metabolic rates and, consequently, have different requirements for caloric intake. Thus, direct comparisons of the absolute surface areas of the GI tracts among various species are not straightforward. One way to normalize the surface areas of the stomach, small intestine, and large intestine across species is to consider these surface areas relative to the total body surface areas of different species. The metabolic rates of most mammals are proportional to body

surface area [53,54]; consequently, the relative surface area serves to normalize the effective absorptive surface based on the metabolic requirements of a given species. The surface areas of the GI tract are presented as both absolute surface area and relative surface area in Table 2.3. (The relative surface area is the absolute surface area of a GI tract region divided by the body surface area.)

Humans are the largest species analyzed in Table 2.3; thus, it is not surprising that they have the largest absolute small intestinal surface area. It is noteworthy, however, that when the basal metabolic rates of the various species are taken into consideration, humans also have the largest relative surface area. The impact of the differences in surface areas on absorption of substances can be appreciated by comparing the relative surface areas of the human small intestine to that of the rat. The human relative surface area is approximately four times greater than that of the rat (Table 2.3). Since the amount of a substance that crosses the enteric mucosa is determined by its flux (amount of mass per unit surface area per unit time), the impact of the increased relative intestinal surface area in humans on absorption is twofold. First, substances that are equally well absorbed in both rats and humans are likely to be absorbed more quickly in humans (i.e., exhibit a higher rate of absorption). Second, substances that are poorly or incompletely absorbed by both species are likely to be absorbed to a greater extent by humans.

It should be noted that the values in Table 2.3 can be altered by physiological changes that occur in response to nutritional challenges. For example, during times of starvation or disease (such as diabetes [58]) or during normal physiologic stress brought on by pregnancy, the mucosa of the rat stomach undergoes hyperplasia [59]. In pregnancy, the mucosal surface area of the small intestine increases as gestation progresses due to a temporary, but progressive, increase in villi height [60]. Further, this condition of increased absorptive surface area is maintained throughout lactation [61]. Changes in effective surface areas also occur as animals age. The villi of the small intestine decrease in height during old age [62–64], leading to a decrease in absorptive surface area, and, consequently, reduced efficiency in the absorption of nutrients and other materials from chyme (see further discussion under Section 2.6).

With respect to the often cited concept that metabolic rates of species are proportional to their surface area raised to the two-thirds power [65], it is interesting that the mucosal surface area of the small intestines among nonruminant eutherian mammals increases approximately in proportion to the 0.6 power of body mass [36].

2.6 MOTILITY AND TRANSIT TIMES

As previously noted, absorption of materials from the intestinal tract is determined not only by the total available surface area but also by the amount of time that substances are in contact with the absorptive epithelium. Most of the alimentary canal is invested with at least two layers of smooth muscle. The muscle fibers of the inner layer are arranged circumferentially relative to the lumen, while the outer layer is arranged parallel to the long axis of the canal. The coordinated, rhythmic contractions of these muscle layers produce intestinal motility, which affects the absorption of substances from the intestinal tract. First, intestinal motility thoroughly mixes the chyme to aid in its digestion. Second, it continually agitates the chyme, pushing it against the enterocyte brush border, thus, aiding in absorption. Finally, intestinal motility propels the chyme

TABLE 2.3 Comparison of Absolute Surface Areas and Surface Areas Relative to Resting Metabolic Rates of the Gastrointestinal Tract and Its Major Subdivisions in Seven Different Species

	Mouse		Rat		Rabbit		Dog		Pig		Monkey		Human	
Body weight (kg)	0.032		0.3		2.6–3.9		10.7–12.6		47		2.7–3.0		70	
Body surface area (BSA; m ²) ^a	0.0066		0.03–0.06		0.23		0.39–0.78		—		0.3		1.8
